Abstract

Valuing American options along simulated stock paths requires an implied volatility (IV) for every option on every date. A stock-return model alone does not provide it. In this study, we built a simulator that assigned IV to American options on simulated dates for any chosen stock model. We fitted parametric and neural IV surfaces to vendor option quotes for 31 tickers. Each surface predicted IV from moneyness and time to expiration. Stock paths came from a jump hidden Markov model with capped daily returns. Each day, every option's implied variance moved partway toward its surface prediction, following the form of the Heston variance equation. Random shocks tended to raise IV when the stock fell. A binomial tree converted IV into option values and price sensitivities. Neural surfaces fitted by sector or ticker matched the quotes more closely than one parametric surface. Their errors still varied by date and carried into dollar prices. Repricing identical stock paths under five ways of updating IV changed option values before expiration and the worst losses from closing short positions early. Payoffs at expiration did not change. In forecasts of later Goldman Sachs and Eli Lilly option prices, stochastic IV did little better than fixed IV. Rerunning the forecasts with the realized stock paths showed that stock-forecast errors caused most misses. The hidden Markov model, an adaptive-volatility model, and a direction-predicting model all predicted stock prices about as accurately as assuming no change. The adaptive-volatility model improved predicted price ranges for Eli Lilly but not Goldman Sachs. The simulator supported reproducible comparisons of IV and stock assumptions but did not forecast better than simpler alternatives. Complete option histories and prices consistent across strikes are needed before simulated prices can replace market data.

1 Introduction

Implied volatility (IV) is the volatility that makes a pricing model, such as that of Black and Scholes [Black and Scholes \[1973\]](#), reproduce an observed option price [Latané and Rendleman \[1976\]](#). An option's IV is therefore backed out of its market price rather than observed on its own. A simulated stock path has no option prices, so it has no IV either. Without an IV, a pricing model cannot value an option on a simulated date. A stock portfolio can be stress-tested or backtested on simulated price paths directly, because each simulated price is the position's value. An option position cannot, because its value on each simulated date also depends on an IV that the simulation does not supply. Those dates matter. Option strategies are judged by their payoffs at expiration but managed on every date before it. A short put that expires worthless can still lose money if the stock falls first and the trader has to close or hedge the position. American options make the earlier dates matter

even more, since the holder may exercise on any of them. A simulation that values options along stock paths therefore needs two parts. The first is a stock model that reproduces the return behavior the stress test or backtest depends on, such as heavy tails and volatility clustering [Cont \[2001\]](#). The second is a rule that assigns every option an IV across strikes and expiration dates and updates it as the simulated stock moves.

Existing approaches address different parts of this problem through their choices of return dynamics, volatility representation, and pricing model. Parametric models such as stochastic alpha beta rho (SABR) and stochastic volatility inspired (SVI) provide compact descriptions of volatility smiles [Hagan et al. \[2002\]](#), [Gatheral \[2004\]](#). Neural networks can learn the pricing map of a specified volatility model, which speeds up its pricing and calibration [Horvath et al. \[2021\]](#), [Bayer and Stemper \[2018\]](#). Models of IV-surface dynamics describe changes in level, skew, and curvature through common factors [Cont and da Fonseca \[2002\]](#), with more recent methods incorporating static arbitrage constraints into surface simulation [Cont and Vuletić \[2023\]](#). Local- and stochastic-volatility models instead place stock and volatility dynamics within a joint pricing model [Dupire \[1994\]](#), [Derman and Kani \[1994\]](#), [Heston \[1993\]](#). Each of these can price options at strikes, expiration dates, or market states that were never quoted. Most, however, either describe the smile on a single date or bring stock dynamics of their own. They are not built to take stock paths from a separately chosen generator as given. That limitation matters when a researcher has already chosen a stock-return generator for how well it matches real returns and wants to vary only the volatility assumptions. Synthetic return generators, from regime-switching models with jumps to generative neural networks, can reproduce important features of equity returns [Cont \[2001\]](#), [Wiese et al. \[2020\]](#), [Alswaidan and Varner \[2026\]](#). Their paths carry no option prices. What is missing is a rule that takes each simulated stock path as given and assigns every option an IV along it. Such a rule would let researchers compare volatility assumptions on identical stock paths. It would be useful only if the resulting prices matched market quotes and stayed free of arbitrage across strikes and expiration dates.

In this study, we built a simulator that assigns IV to American options along stock paths from any chosen synthetic generator. In the simulator, each option’s IV moved partway each day toward the value predicted by an IV surface fitted to market quotes, with random shocks partly tied to the stock’s moves. A binomial tree then converted that IV into the option’s price [Cox et al. \[1979\]](#), [Leisen and Reimer \[1996\]](#). We used the simulator to ask three questions. The first was whether IV surfaces fitted to market quotes were accurate enough to serve as these targets. Surfaces fitted separately to sectors or single stocks matched the quotes better than one surface for all stocks. On later dates, however, their accuracy was uneven, so they served as targets only in part. The second was whether the choice of IV update, from holding IV fixed to the full update with random shocks, mattered when the stock paths stayed the same. It did. The choice of update changed option values before expiration and the worst losses from closing short positions early. An analysis of payoffs at expiration alone would miss these differences. The third was whether the simulator could forecast later option prices. Its forecasts improved little on holding IV fixed, and most of their error came from the stock forecast rather than from IV. Because the IV update cannot correct a missed stock forecast, the simulator is better suited to controlled comparisons of volatility assumptions than to forecasting. Some simulated prices were also inconsistent across strikes, and consistency across expiration dates was not tested. More broadly, the approach turns any synthetic stock generator into a source of option scenarios for stress tests and backtests on hypothetical market paths.

2 Methods

2.1 Simulator overview and stock paths

The simulator worked in two phases. Before any simulation, we fitted IV surfaces to observed option quotes, and each surface predicted an option’s IV from its moneyness and time to expiration. The simulation itself used only these fitted surfaces and needed no further option quotes. It first generated complete stock paths from the Jump Hidden Markov Model (JumpHMM) [Alswaidan and Varner \[2026\]](#) and then moved forward along each path one trading day at a time. On each day, a binomial tree priced each option from the current stock price, the remaining time to expiration, and the option’s current IV, and the same tree supplied its price sensitivities (Greeks). The option’s implied variance then moved partway toward the variance that the fitted surface predicted for its current moneyness and remaining time, with random shocks linked to the stock’s return. Option

prices never fed back into the surfaces or the stock paths, so information flowed in one direction, from the stock price to IV to the option price (Algorithm 1).

The stock paths came from JumpHMM [Alswaidan and Varner \[2026\]](#). We used a pretrained version fitted separately to each ticker’s price history from 2014 to 2024. The model describes each ticker’s excess growth rate with hidden states, and each state draws the growth rate from its own location-scale Student- t distribution, called the state’s emission distribution. A jump mechanism increases visits to tail states. In the original study, this reproduced heavy tails and part of the volatility clustering of equity returns [Alswaidan and Varner \[2026\]](#), two features documented across many markets [Cont \[2001\]](#). The pretrained model covered 424 tickers, each with 50 states fitted on 2,767 trading days. Its growth rates used a time step of $1/252$ year and a risk-free offset of zero. A Student- t copula can link the returns of several tickers [Demarta and McNeil \[2005\]](#), but every scenario reported here simulated one ticker at a time.

For price simulation, we cut off each Student- t emission distribution at a finite bound. The simulated excess growth rate in state k was given by:

$$G_t = \mu_k + \sigma_k Z_t, \quad Z_t \sim t_{\nu_k} \mid |Z_t| \leq b, \quad b = 10, \quad (1)$$

where μ_k and σ_k are the fitted location and scale of state k , ν_k is its degrees of freedom, and the cutoff b is measured in multiples of the scale σ_k . We applied the cutoff only in simulation, and the locations, scales, transition matrix, and jump parameters kept their fitted values. We redrew any value outside the bound before adding the constant drift adjustment (growth shift) and converting log returns to prices, so no stock path was discarded. The cutoff kept the states and the jump mechanism intact and gave the stock price a finite mean and variance at every horizon. Without it, exponentiating Student- t log returns gives an infinite expected stock price, so mean call values and expected short-call losses would have no finite population value [Cassidy et al. \[2010\]](#). To examine sensitivity, we repeated the simulations with a wider cutoff, $b = 20$, using the same contracts, seeds, and evaluation dates and recomputing the normalization constants for each cutoff. Neither cutoff was chosen by forecast performance (Supplementary Tables [S33](#), [S34](#), and [S35](#)).

2.2 Option data and IV surfaces

We downloaded option-chain snapshots daily from Alpaca Markets with a free account. This account supplies Alpaca’s indicative feed, a modified version of the exchange (OPRA) feed [Alpaca Markets \[2026b\]](#). Every quote, midpoint, spread, and reported IV in this study is therefore an Alpaca value, which may differ from exchange quotes and from prices at which trades could execute. The calibration data set contained 457 ticker files from fifteen daily snapshots, and 234,549 observations remained after filtering. The filters kept calls and puts with a positive bid, positive calendar days to expiration (DTE), reported IV strictly between 0.01 and 2.0, and strike/spot between 0.8 and 1.2 inclusive. Spot was the stored closing price of the underlying for that session. Calls and puts entered the same loss, and a contract that appeared in several snapshots counted once per snapshot. The fitting target was the IV that Alpaca reports with each quote. Alpaca documents this IV as a Black–Scholes calculation solved iteratively using the price sensitivity to volatility (Vega) [Alpaca Markets \[2026a\]](#). The April earnings holdout split dates by snapshot label, and the other temporal tests split by underlying-session date (Supplementary Table [S1](#)).

The data covered many tickers, strikes, and expirations but only a short window of dates. We used them to compare a five-parameter log-polynomial surface with neural surfaces shared by all tickers, shared within a sector, or fitted to a single ticker. The log-polynomial follows the compact parametric tradition of SABR and SVI [Hagan et al. \[2002\]](#), [Gatheral \[2004\]](#), and the neural surfaces allow more flexible shapes. We exponentiated each shape function to keep it positive. We imposed neither calendar monotonicity nor strike convexity during fitting, so the fitted surfaces needed separate no-arbitrage checks. The parametric shape was given by:

$$\psi_\beta(\tau, m) = \exp[\beta_1 \ln \tau + \beta_2 \ln m + \beta_3 \ln \tau \ln m + \beta_4 (\ln m)^2 + \beta_5 (\ln \tau)^2], \quad (2)$$

where τ is calendar DTE, $m = K/S$ is moneyness, and $\beta_1, \dots, \beta_5$ are fitted coefficients. The predicted squared IV for ticker i multiplied a ticker level by the shape:

$$\hat{\sigma}_i^2(\tau, m) = \theta_i \psi(\tau, m), \quad \theta_i > 0, \quad \psi(\tau, m) > 0, \quad (3)$$

where θ_i sets the overall IV level of ticker i and ψ sets how IV varies with moneyness and maturity. The same product, evaluated at an option’s current moneyness and maturity, later served as the variance target in the simulation.

The neural surfaces replaced the log-polynomial with the exponential of a neural network (NN) output, given by:

$$\psi_{\text{NN}}(\tau, m; w) = \exp[\text{NN}(\text{std}(\ln \tau), \text{std}(\ln m); w)], \quad (4)$$

where w denotes the network weights and $\text{std}(\cdot)$ standardizes each input with the mean and standard deviation of the training rows. A ticker received its own network only if it had at least 2,000 observations. Tickers below that threshold used their sector's network. Networks fitted to at least 5,000 observations for one ticker, or at least 2,000 observations for a pooled group, had two hidden layers of 16 tanh units ($2 \rightarrow 16 \rightarrow 16 \rightarrow 1$, 337 parameters). Smaller qualifying fits used two hidden layers of 8 units ($2 \rightarrow 8 \rightarrow 8 \rightarrow 1$, 105 parameters). For the earnings analysis, we added two standardized inputs. The first was the signed number of days to the ticker's nearest earnings date, clipped to $[-30, 30]$. The second was the smallest absolute number of days to an earnings date among the ticker's sector peers, clipped to 30. For the three ETFs, both inputs were the smallest absolute number of days to an earnings date among all 28 non-ETF stocks. The resulting network had 369 parameters ($4 \rightarrow 16 \rightarrow 16 \rightarrow 1$). Earnings dates came from the public Yahoo Finance calendar. These inputs entered only the April holdout comparison and a later refit of the July surfaces that tested the earnings explanation, and the Goldman Sachs (GS) and Eli Lilly (LLY) simulations never used them. We fitted the network weights and the ticker log levels jointly by minimizing the mean squared difference between predicted and reported IV, which weights every retained observation equally:

$$\min_{w, \{\ln \theta_i\}} \frac{1}{n} \sum_{j=1}^n \left[\sqrt{\theta_{i(j)}} \psi_{\text{NN}}(\tau_j, m_j; w) - \sigma_{\text{market}, j} \right]^2, \quad (5)$$

where n is the number of observations, $i(j)$ is the ticker of observation j , and $\sigma_{\text{market}, j}$ is its reported IV. We initialized each log level as the logarithm of the squared mean reported IV for that ticker. Training used the Adam optimizer with a decreasing learning rate and at most 2,000 epochs. It stopped after 200 epochs without improvement in training loss, and we kept the weights from the final epoch. A constant can move between $\ln \theta_i$ and the network's output bias without changing the fit. The two are therefore not separately identified, and only their product in (3) can be interpreted without an extra normalization.

2.3 Daily IV updates

The standard Heston model pairs a stock-price diffusion with a square-root process for the stock's instantaneous variance Heston [1993]. That variance follows the stochastic differential equation given by:

$$dv_t = \kappa(\theta - v_t) dt + \sigma_v \sqrt{v_t} dW_t^v, \quad (6)$$

where κ is the mean-reversion rate, θ is the long-run variance, σ_v is the volatility of variance, and W_t^v is a Brownian motion that the standard model correlates with the one driving the stock. We used the same square-root equation for a different quantity. Each option received its own implied-variance state, which we call its IV factor, and that factor evolved along a stock path supplied by JumpHMM. Each factor reverted toward a target read from the fitted surface, and its square root was the volatility input to that option's binomial tree. Each pricing calculation held that volatility constant, and the factor changed only between simulated dates. The factor is therefore the implied variance of one option, not the instantaneous variance of the stock's returns. For an option $a = (i, K, T)$ on ticker i with strike K and expiration T , the factor $v_{a,t}$ reverted toward the target given by:

$$\bar{v}_{a,t} = \theta_i \psi_{\text{NN}}(\tau_t, K/S_t), \quad (7)$$

where S_t is the stock price and τ_t the remaining calendar DTE on date t , so the target moved as the stock price and the time to expiration changed. Each factor started on the fitted surface at entry,

$$v_{a,0} = \bar{v}_{a,0}, \quad (8)$$

and on every date the IV entering the binomial tree was its square root:

$$\sigma_{a,t} = \sqrt{v_{a,t}}. \quad (9)$$

A put and a call on the same stock shared its path and variance shock but kept separate factors and targets. The stock and the factors advanced only on exchange trading days. In the original GS and LLY illustrations, we added a constant to every simulated growth rate so that the average

across paths matched a prespecified annual growth prior. We call this constant the growth shift. We then standardized the one-session log returns across all paths and dates. The comparison of five IV variants instead estimated both constants from a separate pilot simulation. The standardized return shock entering the IV update was given by:

$$Z_{j,t}^S = \frac{\Delta \ln S_{j,t} - \overline{\Delta \ln S}}{s_{\Delta \ln S}}, \quad (10)$$

where $\Delta \ln S_{j,t}$ is the one-session log return on path j at date t , and $\overline{\Delta \ln S}$ and $s_{\Delta \ln S}$ are its mean and standard deviation across paths and dates. The shock to each factor combined this return shock with an independent standard normal shock:

$$Z_{j,t}^v = \rho Z_{j,t}^S + \sqrt{1 - \rho^2} Z_{j,t}^\perp, \quad Z_{j,t}^\perp \sim \mathcal{N}(0, 1), \quad (11)$$

where ρ sets how strongly the factor responds to the stock's return. We fixed $\rho = -0.6$, so IV tended to rise when the stock fell. This ρ is a chosen weight on the return shock, not a correlation estimated from data. Each factor advanced once per trading day by an Euler-type step of the square-root equation, with $\Delta t = 1/252$ and a floor at $v_{\min}$. The step used $Z_{j,t}^v$ in place of a Brownian increment, so its shocks were not exactly normal:

$$v_{a,t+1} = \max \left\{ v_{a,t} + \kappa(\bar{v}_{a,t} - v_{a,t})\Delta t + \sigma_v \sqrt{\max(v_{a,t}, 0)} \sqrt{\Delta t} Z_{j,t}^v, v_{\min} \right\}. \quad (12)$$

We fixed $\kappa = 15$, $\sigma_v = 0.5$, and $v_{\min} = (0.005)^2$ as scenario assumptions. The floor kept the factor positive for the pricer, because an Euler step can fall below zero whether or not these values satisfy the Feller condition [Andersen \[2008\]](#). The code also contains two proposed extensions, a target level that depends on JumpHMM's hidden state and a multiplier driven by visits to tail states. Both were switched off in every reported experiment, so the fitted surface alone set the target and the fixed ρ alone linked IV to stock returns.

2.4 American-option pricing and profit and loss

A binomial tree (lattice) prices an American option by working backward from expiration and taking, at every node, the larger of the value of continuing and the value of exercising immediately [Cox et al. \[1979\]](#), [Broadie and Detemple \[1996\]](#). The Cox–Ross–Rubinstein (CRR) tree sets its up and down moves from the supplied volatility [Cox et al. \[1979\]](#). Alternatives include the moment-matching trees of Jarrow–Rudd and Tian [Jarrow and Rudd \[1983\]](#), [Tian \[1993\]](#) and the Leisen–Reimer tree, which uses the Peizer–Pratt inversion to converge faster as steps are added [Leisen and Reimer \[1996\]](#). Both trees used here took one IV value per option and date. The GS and LLY options ran from April 28 to May 29, 2026, a span of 31 calendar days and 22 trading-day steps after excluding weekends and the May 25 market holiday. The surface and the tree measured time to expiration in calendar days, with $\tau_t/365$ years entering the pricer, while the stock and the factors advanced on the 22 trading-day steps. Dollar-price checks across the calibration data used a 200-step American CRR tree. Scenario prices and Greeks used a 201-step American Leisen–Reimer (LR) tree. Both used a constant risk-free rate of 4.25% and a continuous dividend yield $q = 0$. In low-volatility states, or when the Leisen–Reimer probabilities saturated, an American CRR tree priced the option instead and kept the early-exercise comparison. On each trading day, the simulation priced each option from its current stock price, remaining maturity, and factor, and then advanced the factor toward its moving target. At expiration, the option's intrinsic value replaced the tree price (Algorithm 1).

Algorithm 1 Forward simulation of contract values

Require: JumpHMM model for ticker i ; fitted (θ_i, ψ_i) ; contract (K, T) ; trading dates $d_0, \dots, d_L$; calendar DTE $\tau_0, \dots, \tau_L$; (κ, σ_v, ρ) ; S_0 ; r ; N_p paths; LR tree steps N_{LR} .

Ensure: Stock, variance, IV, and option-value paths.

- 1: Draw N_p JumpHMM stock paths with L trading transitions and emissions truncated as in (1).
 - 2: Compute $Z_{j,\ell}^S$ by standardizing all simulated one-session log returns as in (10).
 - 3: Draw $Z_{j,\ell}^\perp \sim \mathcal{N}(0, 1)$ once per path and transition; set $Z_{j,\ell}^v \leftarrow \rho Z_{j,\ell}^S + \sqrt{1 - \rho^2} Z_{j,\ell}^\perp$ and reuse it for every contract.
 - 4: **for** contract a and path j **do**
 - 5: $v_{a,0}^{(j)} \leftarrow \theta_i \psi_i(\tau_0, K/S_0)$
 - 6: **for** $\ell = 0$ **to** $L - 1$ **do**
 - 7: $\sigma_{a,\ell}^{(j)} \leftarrow \sqrt{v_{a,\ell}^{(j)}}$
 - 8: $P_{a,\ell}^{(j)} \leftarrow \text{LR}_{N_{LR}}(S_{j,\ell}, K, \sigma_{a,\ell}^{(j)}, \tau_\ell/365, r)$
 - 9: $\bar{v}_{a,\ell}^{(j)} \leftarrow \theta_i \psi_i(\tau_\ell, K/S_{j,\ell})$
 - 10: Update $v_{a,\ell+1}^{(j)}$ with the floored Euler step in (12) using $\Delta t = 1/252$.
 - 11: **end for**
 - 12: $P_{a,L}^{(j)} \leftarrow \max\{\phi(S_{j,L} - K), 0\}$, where $\phi = 1$ for a call and $\phi = -1$ for a put.
 - 13: **end for**
 - 14: **return** all paths.
-

For a short position that sold the option at the captured indicative midpoint p_0 , profit and loss (P&L) at expiration was given by:

$$\Pi_T^{\text{put}} = p_0^{\text{put}} - \max(K - S_T, 0), \quad \Pi_T^{\text{call}} = p_0^{\text{call}} - \max(S_T - K, 0), \quad (13)$$

where S_T is the JumpHMM stock price at expiration. This P&L depended only on S_T , the strike, and the premium, so the IV updates changed option prices and Greeks before expiration but not the payoff of a position held to expiration. All premiums, option values, and P&L are in dollars per share, so amounts for a standard 100-share contract are 100 times these values. We calculated Greeks by central finite differences on the same Leisen–Reimer tree. Delta measures the price’s sensitivity to the stock price, and gamma measures how delta changes with the stock price. Delta and gamma used stock-price bumps of $\pm 1.5\%$, and Vega used volatility bumps of ± 0.005 and is reported per volatility percentage point. We assumed execution at the observed mid, no transaction costs, no margin constraint, no premium financing, no early assignment before the plotted horizon, and no discrete dividends.

2.5 Comparison of five IV variants

To find which parts of the IV update changed option values before expiration, we compared five IV variants on the same stock paths, options, entry premiums, and pricing assumptions. Frozen IV kept each option’s IV at its fitted entry value. The direct surface set the factor to the surface target, $v_{a,t} = \bar{v}_{a,t}$, on every date. Deterministic mean reversion used the update in (12) without shocks ($\sigma_v = 0$). The uncoupled stochastic factor added shocks unrelated to stock returns ($\sigma_v = 0.5$, $\rho = 0$). The full factor, also called the coupled factor, linked those shocks to stock returns ($\sigma_v = 0.5$, $\rho = -0.6$). All three variants that evolved used $\kappa = 15$. Every variant started from the same fitted entry IV, and the two stochastic variants reused the same independent normal shocks. We ran this paired comparison, which we call the IV ablation, with three seeds per ticker (20260429, 20260430, and 20260431) and 1,000 paths per seed. A separate 10,000-path pilot simulation (seed 20260905) supplied the growth shift toward the 10% annual prior and the mean and standard deviation of one-session log returns. We fixed these constants before generating the evaluation paths. Unlike the original illustrations, the evaluation paths were therefore never recentered or standardized with their own future values. The pilot and evaluation simulations each used 22 trading-day steps, and each simulated return was applied exactly once after the initial stock price.

The primary endpoint closed the position after ten trading days, on May 12 with 17 calendar days to expiration. Secondary endpoints closed it after five, fifteen, and twenty trading days. The P&L

from closing a short position early, and its difference from the direct surface on the same path, were given by:

$$\Pi_{a,t}^{(b,j)} = p_{a,0} - P_{a,t}^{(b,j)}, \quad D_{a,t}^{(b,j)} = \Pi_{a,t}^{(b,j)} - \Pi_{a,t}^{(\text{surface},j)}, \quad (14)$$

where b denotes the IV variant, j the shared stock path, and $P_{a,t}^{(b,j)}$ the option's price on date t . We reported mean P&L, its standard deviation, the 5% quantile, and 5% expected shortfall, defined as mean P&L at or below that quantile. The Monte Carlo standard error of the mean paired difference was $s_D/\sqrt{n}$, where s_D is the standard deviation of D across n paths. Mean absolute price differences measured the size of the changes on individual paths, which can cancel in the mean. We reported each seed separately and also pooled the 3,000 paths per ticker. These standard errors measure simulation noise with the fitted models and pilot constants held fixed.

We also checked that entry prices and payoffs at expiration agreed exactly across variants, and we examined the numerical accuracy and strike consistency of the prices in between. The numerical check compared 201-step and 401-step prices on the first twenty paths of every evaluation seed after ten and twenty trading days. A separate check across strikes (the strike audit) priced calls and puts at eleven fixed strikes from 0.8 to 1.2 times the entry stock price, all with the scenario expiration and the same shocks. It used the first fifty paths of the first seed at entry and after ten and twenty trading days. At both tree depths, we checked intrinsic-value and upper price bounds, monotonicity in strike, vertical-spread bounds, and convexity in strike. A convexity violation was the dollar amount by which a price exceeded the straight line between its neighbors, and we counted violations larger than \$0.01 per share. Entry prices were counted once per variant and option type. Passing these checks is necessary for prices to be consistent across strikes. The audit compared strikes within one expiration date, so consistency across expiration dates and over time remained untested.

2.6 Tests on later dates

We evaluated later dates in two stages, to separate how well the surfaces transferred across dates from how well the simulator forecast complete option paths. The first stage used 58 capture dates through July 17, 2026. In each of 53 folds, we fitted the sector networks to the first k dates and predicted the next date, for $k = 5, \dots, 57$. This stage kept the original filters and capture-date labels, used the two surface inputs, and standardized the inputs using each training fold alone. An independent reconstruction of the saved row counts found that its 986,492 accepted observations had no crossed or missing asks and no missing or nonpositive displayed bid or ask sizes (Supplementary Table S19). Each prediction used the later date's stock price to compute moneyness. This stage therefore measured how well the surface predicted IV on a new date given the stock price. Stock forecasts and the IV updates entered only the second stage. The second stage fitted six sector networks once, using 1,173,538 observations from 68 trading sessions ending July 31 (Supplementary Table S19). The architectures and training schedule matched the two-input sector model, with seed 42 and at most 2,000 epochs. We saved each network's final weights, ticker levels, and training-only standardization. The later sample contained 425,061 filtered IV observations across 23 sessions from August 4 through September 4. It served only as the final test, after the architectures, fitting windows, parameters, and seeds had been fixed.

Before fitting or selecting options, the second stage checked when each file had been downloaded (the capture audit). The download script recorded each retrieval time in UTC and stored the underlying's closing price with each option row. We accepted files retrieved after 20:00 UTC on the session date and before 13:30 UTC on the next trading session. This rule admitted overnight downloads of the previous close and excluded twenty repeat downloads taken during trading hours (Supplementary Table S19). We kept the latest eligible file per ticker and session and one row per exact option symbol. A two-sided quote needed a finite positive bid, an ask no lower than the bid, and positive displayed sizes. Surface fitting also required the original IV and moneyness ranges and a positive DTE recomputed from the expiration and the session date. Only files retrieved by the end of July 31 could enter training. Retrieval times record when each file was downloaded, not when each quote was set. Some quotes may therefore have been stale, and stock and option prices may come from slightly different moments, which affects both the IV errors and the dollar-price errors.

The forecast test used GS and LLY at successive forecast dates (origins) in August and early September. At each origin, we forecast one put and one call with 25 to 45 calendar DTE over planned horizons of one and five trading sessions. For each option type, we chose the expiration nearest 31 DTE and then the strike nearest $K/S = 0.95$ for puts or 1.05 for calls. Ties went to the earlier

expiration and then by symbol, and the choice used only data available at the origin. We matched each chosen option at its exact endpoint session and recorded a missing endpoint as missing, without substituting another option or date. The data collection kept only certain maturity ranges each day, so none of these roughly one-month options was observed five sessions later (Supplementary Table S20). We kept their one-session evaluation and added a separate shorter-maturity cohort with 10 to 21 DTE, choosing the expiration nearest 14 DTE with the same strike and tie rules. We made this change, and recorded it in the experiment protocol, before looking at aggregate forecast errors. The five-session results therefore come from the shorter cohort. All five IV variants started from the option’s observed IV at the origin. So that the fitted surface’s starting level error would not enter the comparison, we rescaled the surface target once at the origin:

$$\bar{v}_{a,t}^* = \sigma_{a,0,\text{obs}}^2 \frac{\bar{v}_a(S_t, \tau_t)}{\bar{v}_a(S_0, \tau_0)}, \quad (15)$$

where $\sigma_{a,0,\text{obs}}$ is the option’s observed IV at the origin. The rescaled target started at the observed IV and kept the surface’s relative changes with stock price and time to expiration. This rescaling applied only to the forecast test, and the IV ablation kept its fitted starting values. Frozen IV held the observed origin value, the direct surface followed $\bar{v}_{a,t}^*$, and the three evolving variants reverted toward $\bar{v}_{a,t}^*$ with the parameters used in the ablation. Each origin used 1,000 JumpHMM paths, with the same normal shocks for every IV variant. The starting hidden state was drawn from the stationary distribution of the model’s transition matrix, with no jump episode in progress, so recent returns did not inform it in the original forecast. A separate 10,000-path pilot per ticker fixed the growth shift toward the 10% annual prior and the one-session return standardization before the evaluation paths were drawn. A Gaussian random walk with zero log drift and the pilot’s return standard deviation served as a stock benchmark. At each origin, the stock price and IV were updated to the latest observations while the fitted parameters stayed fixed. The test therefore evaluated forecasts issued at successive origins with the surfaces and model parameters fixed on July 31.

We scored the mean forecast option value against the later bid–ask midpoint, with mean absolute error (MAE) as the prespecified primary metric. We also scored the median forecast, to separate the choice of point summary from the IV comparison. Signed error, root mean squared error (RMSE), and the share of forecast means inside the quoted spread served as additional price diagnostics. To score the whole forecast distribution, we used the empirical continuous ranked probability score (CRPS) [Gneiting and Raftery \[2007\]](#). The CRPS rewards forecasts concentrated near the observed value and penalizes probability placed far from it, and it is given by:

$$\text{CRPS} = \frac{1}{N} \sum_{j=1}^N |P_j - y| - \frac{1}{2N^2} \sum_{j=1}^N \sum_{k=1}^N |P_j - P_k|, \quad (16)$$

where $P_1, \dots, P_N$ are the simulated option values, y is the observed midpoint, and smaller values indicate better forecasts. We also reported the coverage and width of central 90% intervals. Scores were averaged across matched options within each ticker and origin, then across dates, and stock forecast scores were reported separately. A diagnostic repeated the IV updates along the observed stock path whenever every intervening session was available. Because it used the realized stock path, it measured how much of the option error came from the stock forecast. A second diagnostic repriced each option in the same tree with the IV reported at the endpoint, to isolate pricing discrepancies. All monetary scores are in dollars per share. Overlapping horizons and shared market moves made forecast dates and options dependent. The market evidence therefore rests on the origins, not on the number of simulated paths. The illustrated forecast was the earliest GS origin in the shorter-maturity cohort with both options observed at the five-session endpoint, a rule that ignored forecast errors.

2.7 Stock forecast benchmarks

The option forecast errors led us to evaluate the stock forecasts separately. We first checked how returns were scaled and how prices were rebuilt from them. We then repeated the 2026 stock forecasts with the starting hidden state inferred from recent returns. This diagnostic kept the fitted parameters and, during state inference, tracked the remaining length of any jump episode in progress. We then compared four stock forecast methods: the saved 2014–2024 JumpHMM, an unchanged-price benchmark, an adaptive-volatility model, and a direction-predicting model. The JumpHMM forecasts kept the model’s long-run starting state and pilot growth shift. The adaptive-volatility model

drew Gaussian log returns and updated its daily variance with an exponentially weighted moving average (EWMA) of squared log returns [J.P. Morgan/Reuters \[1996\]](#). The direction-predicting model used the same variance and added a daily drift estimated by regression. The regression inputs were the stock’s cumulative returns over its latest one, five, and twenty valid days and SPY’s cumulative return over its latest five valid days. Each feature was divided by the square root of its window length and by its own asset’s EWMA volatility at the origin, so SPY’s feature used SPY’s volatility. A ridge penalty with no intercept shrank the coefficients toward zero [Hoerl and Kennard \[1970\]](#). The two models were given by:

$$a_t = \lambda a_{t-1} + (1 - \lambda) u_t^2, \quad \log \frac{S_{t+h}}{S_t} = h\mu_t + \sqrt{a_t} \sum_{j=1}^h Z_j, \quad Z_j \sim \mathcal{N}(0, 1), \quad (17)$$

where $u_t = \log(S_t/S_{t-1})$ is the observed daily log return, a_t is the estimated daily variance at origin t , λ is the EWMA decay, h is the horizon in trading days, and μ_t is the daily drift. The adaptive-volatility model set $\mu_t = 0$, and the direction-predicting model used the regression estimate. Drift and variance stayed fixed within each forecast horizon, so neither model used future stock or market returns. The unchanged-price benchmark gave only a point forecast, with no uncertainty interval. These stock tests left the paths used in the option forecasts and the IV ablation unchanged.

We chose the settings of these two models on annual validation blocks from 2019 through 2024. Each block’s regression fit and feature scaling used only earlier data. We chose one EWMA decay and one ridge penalty for both tickers, weighting each ticker, validation year, and horizon equally. Candidate decays were 0.80, 0.90, 0.94, 0.97, and 0.99, and ridge penalties ranged from 0.01 to 1000 and included the zero-drift limit. Decay selection minimized Gaussian log loss for cumulative log returns, while penalty selection minimized squared cumulative-return error divided by forecast variance. After selection, we fitted the regression on 2014–2024 observations and froze its coefficients and scaling. The 2025 test supplied 249 one-session and 245 five-session origins per ticker. The August–September 2026 test kept the original 21 one-session and 17 five-session stock outcomes per ticker. All methods used identical starting prices and endpoints. Features and variance at each origin used only data available at that time. Missing closes were left as gaps, so every return used spanned one trading day. Each stochastic model used 10,000 paths per origin and three fixed seeds, and the adaptive-volatility and direction-predicting models shared the same Gaussian shocks. We reported the MAE of the median forecast and the RMSE of the mean forecast, because the median minimizes expected absolute error and the mean minimizes expected squared error [Hyndman and Athanasopoulos \[2021\]](#). We also reported CRPS and the coverage and width of central 90% intervals. Scores were averaged across dates within each simulation seed and then across seeds. We proposed these two models after seeing the original 2026 misses, although their settings came from the 2019–2024 validation blocks. We therefore reported the two periods separately and treated the 2026 follow-up as exploratory. Every JumpHMM simulation used the truncated emissions in (1), which also supplied the likelihoods for inferring the starting state. Neither the adaptive-volatility model nor the direction-predicting model depended on the truncation.

3 Results

We fitted parametric and neural surfaces to the calibration data and observed lower in-sample IV error as the surfaces became more flexible and were shared by fewer tickers (Table 1). The filtered data contained 234,549 observations from 31 tickers across fifteen snapshots and six market groups (Supplementary Tables S2 and S1). Every model used the same loss and kept a separate level for each ticker. Root mean squared error (RMSE) measured agreement with reported IV in volatility percentage points. Replacing the global parametric shape with a global neural surface reduced pooled in-sample error from 12.48 to 11.47 points, and sector networks reduced it to 10.24 points. The sector networks improved all six groups, most in exchange-traded funds (ETFs) and financials (Supplementary Table S3). Technology and healthcare kept the largest errors and contained the weakest individual ticker fits (Supplementary Table S7). These remaining differences motivated separate surfaces for tickers with enough observations. Giving each such ticker its own network, and keeping sector networks for the rest, reduced pooled error to 9.73 points, 22% below the parametric surface, and most qualifying tickers improved (Supplementary Table S4). We next asked whether the fits held on individual dates, in dollar prices, and on later dates.

Table 1: In-sample IV RMSE on 234,549 observations, reported in volatility percentage points. Each model fitted one ticker level jointly with its shape parameters. The final row used per-ticker neural surfaces for the 29 qualified tickers and sector surfaces for PFE and BMY.

Model	RMSE	Reduction from parametric
Parametric shape, global	12.48	reference
Neural shape, global	11.47	8.1%
Neural shape, six sectors	10.24	17.9%
Neural shape, per-ticker with fallback	9.73	22.0%

Figure 1: In-sample comparison of the implied volatility (IV) observed on May 11, 2026 with surfaces fitted across all fifteen calibration snapshots. Panels show (a) SPY, (b) NVDA, (c) MSFT, (d) LLY, (e) GS, and (f) AVGO, with 7, 7, 9, 11, 11, and 9 calendar days to expiry, respectively. Circles and diamonds distinguish reported call and put IV. Solid, dashed, and dotted curves show per-ticker neural, sector neural, and global parametric fits. The MSFT and LLY fits overpredict IV near the money (Supplementary Table S5).

We then compared the fitted surfaces with the May 11 observations and found errors in the overall IV level on that date that carried into option prices (Figs. 1 and 2). The surfaces had been fitted on all fifteen snapshots, including May 11, so the comparison was in-sample. Near the money, the per-ticker fits exceeded observed IV by an average of 9.45 percentage points for MSFT and 7.90 points for LLY (Fig. 1; Supplementary Table S5). The biases were small for SPY and GS, and the fit underpredicted AVGO by 5.37 points. These errors occurred at observed contracts, and a surface whose only inputs are moneyness and maturity cannot shift its level for one date. To measure the effect on prices, we priced each option with its fitted IV in the American tree and compared each dollar error with the local bid–ask half-spread. We used the half-spread because the same IV error moves prices by different amounts across contracts. Only about one third of the fitted SPY, NVDA, and LLY prices fell within the half-spread around the mid, compared with 88% for GS (Fig. 2; Supplementary Table S6). The largest median absolute error, \$4.01 per share, was for LLY. Repeating the calculation with each contract’s reported IV in the same tree cut the LLY median error six-fold, to \$0.67 per share. The surface’s IV level on that date was therefore a major source of the price error. Even with the reported IV, the American tree missed some captured mids. A better pooled fit therefore left errors on individual dates, and dollar prices needed their own check.

Figure 2: In-sample comparison of CRR American-option prices with Alpaca indicative mids across moneyness for SPY, NVDA, LLY, and GS on May 11, 2026. Errors are tree price minus indicative mid. Curves show prices from the parametric, sector, and per-ticker surfaces and, for reference, from the reported IV. The gray ribbon is the median local bid–ask half-spread by moneyness bin. A point inside the ribbon has an absolute pricing error below that local half-spread.

We next withheld dates from training and observed higher errors on those dates, which earnings-calendar inputs reduced on one fixed holdout (Table 2). Removing May 11 and retraining the sector networks on the other fourteen dates gave pooled error of 10.21 volatility percentage points on the training data and 10.89 points on the holdout (Supplementary Table S8). Error rose most in energy and retail, so the small pooled gap hid differences among sectors. A separate temporal split then tested whether calendar inputs added information beyond moneyness and maturity. Configuration A used those two inputs alone. Configuration C added the distances to the ticker’s and its peers’ earnings dates, on exactly the same training and test rows. The added inputs reduced error on the

two-day holdout from 13.03 to 11.98 volatility percentage points. Several technology tickers with nearby peer reports improved, although not every ticker did (Supplementary Table S9). Configuration B removed observations near earnings before fitting the two-input model and gave similar training and test errors. Because it discarded most observations and changed both samples, it cannot isolate earnings as the cause of the original gap. Transfer to new dates was therefore limited, and earnings inputs helped on the one holdout tested.

Table 2: Temporal-holdout comparison. Training used six snapshots labeled April 14 through April 22, 2026, and testing used April 23–24. Every test ticker appeared in training. Errors and gaps are in volatility percentage points. Configuration B used different row sets from A and C.

Configuration	N_{tr}	N_{te}	Train RMSE	Test RMSE	Gap
A: pooled, two inputs	103,897	26,833	8.05	13.03	+4.99
B: non-earnings, two inputs	29,383	4,516	8.02	7.96	−0.06
C: earnings-aware, four inputs	103,897	26,833	7.61	11.98	+4.36

Having evaluated the surfaces, we simulated complete GS option paths and observed that option values tracked the stock while the put and call IV followed different paths (Figs. 3 and 4). We selected one put and one call for each of GS and LLY from the April 28 capture, all expiring on May 29 (Supplementary Tables S11 and S12). The original illustrations used 1,000 stock paths per ticker and a separate IV factor for each option, with the fixed settings in Supplementary Table S10. Before expiration, the put and call factors followed different targets as moneyness and calendar DTE changed (Fig. 4). The LLY paths used the same calculation with LLY’s own fitted return distribution and a higher fitted IV level (Supplementary Figs. S2 and S3). For both tickers, the Greeks along each path showed delta approaching ± 1 on paths heading toward exercise, gamma concentrating near the strike, and Vega declining toward expiration (Supplementary Figs. S1 and S4). The surfaces included observations from the scenario period, so these paths show how the model behaves. The tests on later dates evaluated forecasts with separate fits.

We next held each short position to expiration and observed that the seller usually kept the full premium but faced losses in the lower tail (Supplementary Tables S11 and S12). In GS, the short put kept its full premium on 74.0% of paths and the short call on 67.7%. The worst 5% of outcomes, however, lost at least \$58.96 per share for the put and \$86.18 for the call, 3.6 and 5.4 times their entry premiums. Those less frequent losses left mean P&L positive for the put but negative for the call. The market heuristic $1 - |\Delta|$, which estimates the chance of keeping the premium from the quoted delta, gave 70.5% and 67.2% for the same contracts. The LLY put and call kept their premiums on 80.7% and 79.3% of paths, and both had positive mean P&L. These frequencies exceeded the heuristic by 11.0 and 10.2 percentage points, larger gaps than in GS. Agreement between the heuristic and the simulated frequencies therefore depended on the ticker and scenario. Quote delta comes from a risk-neutral pricing calculation, whereas the simulated frequencies came from real-world stock paths. Because P&L at expiration depended only on the stock path, strike, and premium, these results reflected the return model and the contracts, not the IV updates. Testing the IV updates required changing them while holding the stock paths fixed.

Figure 3: Simulated evolution of GS stock prices (a), put values (b), and call values (c) along 1,000 paths between April 28 and May 29, 2026. Time is measured in calendar days from April 28. Black curves show the median at each date, and shaded bands contain the middle 90% of values. Red and blue curves show group medians for paths ranked in the 1st–5th and 95th–99th percentiles of terminal stock price. Option values are dollars per share and represent the cost of repurchasing the contract for a short seller. Entry premiums were \$16.51 per share for the put and \$16.09 for the call.

Figure 4: Simulated evolution of annualized IV at the GS put strike (a) and call strike (b). These IV paths come from the scenario in Fig. 3. Both panels express IV as percentages on the same vertical scale. Curves show pointwise medians across all 1,000 paths and within the terminal-stock groups defined in Fig. 3. Shading shows the 5th–95th percentile band. Time is measured in calendar days from April 28, 2026, and stops before expiration because the payoff at expiration does not depend on IV.

We therefore repriced the four scenario options under five IV variants on identical stock paths and found that the IV update changed option values before expiration and the lower tail of early-closing P&L (Fig. 5; Supplementary Table S13). Contracts, entry premiums, and pricing assumptions stayed fixed, so any price difference came from the IV update. After ten trading days, the full factor changed prices by a mean absolute \$1.77–\$2.41 per share relative to the direct surface. For the GS put, the \$1.77 mean absolute change was about 38 times the \$0.05 decrease in mean P&L, which had a paired Monte Carlo standard error of \$0.04. Positive and negative differences therefore largely canceled across paths. Frozen IV and deterministic mean reversion also gave prices that differed from the direct surface. The moving target, and the lag with which the factor followed it, therefore affected prices even without random shocks. Comparing the coupled and uncoupled factors on the same paths isolated the effect of linking IV shocks to stock returns (Fig. 5). For both tickers, short-put P&L declined most on falling-stock paths, and short-call P&L improved most on rising-stock paths. Coupling also changed the lower tail of short-position P&L, measured by 5% expected shortfall, where more negative values mean larger losses. Negative coupling moved the GS put’s expected shortfall from $-\$62.98$ under the uncoupled factor to $-\$64.60$ under the full factor. The GS call’s expected shortfall improved from $-\$71.53$ to $-\$69.82$, and the LLY options moved in the same directions (Supplementary Table S13). The full factor’s mean absolute price differences were similar across the three evaluation seeds (Supplementary Table S14). All variants gave identical entry prices and payoffs at expiration.

Figure 5: Effect of linking IV shocks to stock returns on short-option P&L before expiration, by stock return, after ten trading days for (a) GS and (b) LLY. Each difference is coupled-factor P&L ($\rho = -0.6$) minus uncoupled-factor P&L ($\rho = 0$) on the same stock path, with the same independent normal shocks. Negative values indicate worse short-position P&L under coupling. The 3,000 paths per ticker are sorted by stock return and divided into ten groups of 300. Symbols show each group’s median P&L difference at its median stock return, and lines connect the symbols. Shaded bands span each group’s 25th–75th percentiles. These bands describe variation across paths, not confidence intervals. Red circles denote puts and navy diamonds denote calls. All prices are evaluated on May 12, 2026, with 17 calendar days to expiration.

We then refined the tree and checked prices across strikes, and found that the variant differences exceeded numerical error but that some GS prices violated necessary strike conditions (Supplementary Tables S14 and S15). Increasing the tree from 201 to 401 steps changed sampled prices by at most \$0.0017 per share (Supplementary Table S14). That change was more than two orders of magnitude below the mean absolute differences among IV variants (Supplementary Table S13). No factor reached the variance floor in the four scenario options (Supplementary Table S14). Strike/spot did leave the training interval on 0.7–2.9% of path dates before expiration across tickers, options, and seeds, so some prices used extrapolated surface values (Supplementary Table S14). At 401 steps, the GS direct surface exceeded the \$0.01 convexity tolerance in 178 of 1,818 tested strike triples, with a largest excess of \$0.113 per share (Supplementary Table S16). Each convexity violation corresponds to a butterfly spread priced below zero. The GS full factor had three monotonicity violations

among 2,020 adjacent-strike comparisons, with a maximum of \$0.013 (Supplementary Table S16). These violations persisted at the higher tree depth (Supplementary Table S16), whereas no LLY variant violated the tested conditions at the stated tolerance. Pricing each option accurately on its own therefore left the GS prices inconsistent across strikes.

We extended the surface evaluation beyond the original April–May window and observed uneven accuracy on later dates (Supplementary Tables S17 and S18). In the expanding-window test, two-input sector networks predicted 53 successive held-out capture dates through July 17. The median test RMSE was 9.92 IV percentage points, but individual folds ranged from 7.68 to 19.25 points (Supplementary Table S17). We then fitted one set of sector surfaces through July 31 and scored them on the 23 later sessions from August 4 through September 4. Pooled RMSE rose from 10.79 points in training to 14.75 points on the held-out sessions (Supplementary Table S18). The fitting window, capture audit, and evaluation dates differed from those of the earlier folds, so the two sets of errors cannot be compared directly. The GS surface had held-out RMSE of 6.30 points and overpredicted IV by 0.88 points on average. For LLY, RMSE was 9.96 points and the overprediction was 4.61 points, more than five times the GS bias (Supplementary Table S18). Even with the larger data set, a fixed surface level still lagged later market IV. This lag motivated a separate forecast comparison in which all IV variants started from the observed IV at the origin and differed only in how they evolved afterward.

We next compared option forecasts with later observations of the same options and found nearly identical errors under the coupled factor and frozen IV (Table 3). None of the 36 eligible roughly one-month options per ticker was observed again five sessions later, so these options were scored after one session only (Supplementary Table S20). That comparison kept 34 quotes across 17 origins per ticker. Coupled-factor MAE was \$3.79 per share for GS and \$6.08 for LLY, compared with \$3.80 and \$6.11 under frozen IV (Supplementary Table S21). The shorter-maturity cohort supplied five-session outcomes for 34 GS and 30 LLY quotes across 17 origins per ticker. Coupling again reduced the MAE of the forecast mean only slightly, to \$4.19 from \$4.21 under frozen IV for GS and to \$11.59 from \$11.62 for LLY. It improved date-level MAE on six of seventeen GS origins and nine of seventeen LLY origins, so these small average reductions were not consistent across dates (Table 3). Scoring the forecast median instead lowered GS coupled-factor MAE to \$2.48 and gave LLY an MAE of \$11.79, again close to frozen IV (Supplementary Table S25). The coupled factor’s CRPS was also close to that of frozen IV, at 2.01 versus 2.02 for GS and 8.93 versus 8.99 for LLY (Table 3). Date-weighted coverage of the central 90% intervals was 100% for GS but 67.6% for LLY, 22 percentage points below the nominal level. At the earliest eligible GS origin, the coupled and frozen-IV mean forecasts nearly coincided, while the observed call value fell below both (Fig. 6).

Table 3: Five-session option forecasts for the shorter-maturity cohort, selected with 10–21 calendar DTE at each origin. Scores average matched options within each ticker and origin before averaging dates. The MAE scores the forecast mean. Monetary quantities (MAE, CRPS, and central 90% interval width) are in dollars per share, and coverage is date-weighted. Dates better counts the origins on which a variant’s date-level MAE was below that of frozen IV. Every IV variant uses the same stock paths, origin IV, and matched quotes.

Ticker	IV variant	Dates	Quotes	MAE	CRPS	Coverage (%)	Width	Dates better
GS	Frozen IV	17	34	4.21	2.02	100.0	25.64	–
GS	Direct surface	17	34	4.86	2.16	67.6	24.01	2/17
GS	Mean reversion	17	34	4.26	2.02	100.0	25.62	1/17
GS	Uncoupled factor	17	34	4.24	2.03	100.0	25.69	3/17
GS	Coupled factor	17	34	4.19	2.01	100.0	25.65	6/17
LLY	Frozen IV	17	30	11.62	8.99	73.5	28.98	–
LLY	Direct surface	17	30	11.62	9.05	55.9	26.68	7/17
LLY	Mean reversion	17	30	11.62	8.99	73.5	28.83	7/17
LLY	Uncoupled factor	17	30	11.61	8.97	73.5	28.83	9/17
LLY	Coupled factor	17	30	11.59	8.93	67.6	28.91	9/17

Figure 6: Five-session forecasts of GS stock prices (a), put values (b), and call values (c), compared with observations from August 4 to August 11, 2026. The put strike is \$1,000, the call strike is \$1,105, and both options expire on August 21. Forecasts use the July-cutoff surface and information available at the August 4 origin. Navy curves show forecast means from 1,000 stock paths, with the coupled factor used for option values. Shading spans the central 90% of simulated values. Red dashed curves show frozen-IV mean option forecasts on the same stock paths. Black points show observed stock closes and option midpoints, with vertical bars spanning Alpaca’s indicative bid and ask. Time is measured in trading sessions from the origin. This is the earliest GS origin with both selected shorter-maturity options observed at the five-session endpoint.

We then replaced the simulated stock paths with the observed paths and found that stock-forecast error accounted for most of the option-price error (Supplementary Table S22). Every intervening stock price was observed for thirteen five-session origins per ticker, which gave 26 matched GS quotes and 24 LLY quotes. On these cases, the substitution cut coupled-factor MAE 3.8-fold for GS, from \$4.62 to \$1.23 per share, and 5.4-fold for LLY, from \$10.61 to \$1.95 (Supplementary Table S22). Because the observed path was unknown at the origin, this diagnostic located the source of the error. Within the diagnostic, frozen IV had lower point errors, \$1.07 for GS and \$1.74 for LLY, and the uncoupled stochastic factor had lower CRPS than the coupled factor for both tickers. For the stock itself, JumpHMM also gave no point-forecast advantage. Its five-session stock MAE was \$16.85 for GS and \$49.83 for LLY, compared with \$16.17 and \$48.64 for a Gaussian random walk (Supplementary Table S23). Repricing each shorter-maturity option at its endpoint with its reported IV reduced five-session option MAE to \$0.14 for GS and \$0.34 for LLY. Every repriced value lay within its observed bid–ask interval (Supplementary Table S24). Refining the tree on sampled paths changed prices by at most \$0.0026 per share across the two cohorts, below the forecast errors (Supplementary Table S26). Stock-forecast error therefore dominated the option-price misses, smaller errors remained in the IV and pricing inputs, and no IV variant was reliably better than the others.

We next asked whether a different stock forecast could reduce these misses without future information, and found that every tested method forecast stock prices about as accurately as an unchanged-price benchmark (Table 4). Checks of return scaling and of prices rebuilt from the saved paths found no error in converting annualized log growth to daily prices. Inferring the starting state from recent returns did not materially improve five-session median forecasts. Median-based stock MAE changed from \$16.28 to \$16.36 for GS and from \$49.58 to \$49.40 for LLY (Supplementary Table S29). Under the fitted transitions, the starting state’s influence on the forecast distribution largely disappeared within a few sessions. We then compared JumpHMM with the unchanged-price benchmark, the adaptive-volatility model, and the direction-predicting model, using earlier data to select the settings of the last two. Validation on 2019–2024 data selected an EWMA decay of 0.97 and the zero-drift limit of the direction-predicting model’s regression (Supplementary Table S30). The stock and SPY return features therefore added no signal about direction under this criterion, so the direction-predicting forecasts were identical to the adaptive-volatility forecasts. Testing the models with fixed settings in 2025 supplied 245 five-session origins per ticker, more than fourteen times the 17 in the 2026 case study. In both periods, median-forecast errors stayed close to those of the unchanged-price benchmark.

Table 4: Five-session stock forecasts in 2025 and August–September 2026. Each ticker has 245 origins in 2025 and 17 in 2026. The MAE scores the forecast median. Monetary quantities (MAE, CRPS, and central 90% interval width) are in dollars per share. Scores average dates within each of three 10,000-path simulation seeds and then average the seeds. Adaptive volatility denotes the Gaussian model with EWMA decay 0.97 selected on historical data. Historical selection set the direction-predicting model’s drift to zero, which made it identical to the adaptive-volatility model, so the table omits it. The unchanged-price benchmark has no uncertainty interval. The last column counts origins on which the adaptive-volatility model had lower date-level CRPS than JumpHMM.

Year	Stock	Model	Median MAE	CRPS	Coverage (%)	Width	Dates with lower CRPS
2025	GS	JumpHMM	22.31	16.22	84.4	84.71	–
2025	GS	Unchanged	22.61	22.61	–	–	–
2025	GS	Adaptive volatility	22.62	16.32	89.8	94.86	103/245
2025	LLY	JumpHMM	39.10	29.60	69.9	100.40	–
2025	LLY	Unchanged	39.37	39.37	–	–	–
2025	LLY	Adaptive volatility	39.35	28.57	84.4	151.37	131/245
2026	GS	JumpHMM	16.25	13.03	100.0	129.05	–
2026	GS	Unchanged	15.51	15.51	–	–	–
2026	GS	Adaptive volatility	15.48	15.58	100.0	176.18	2/17
2026	LLY	JumpHMM	49.44	35.60	70.6	147.26	–
2026	LLY	Unchanged	49.37	49.37	–	–	–
2026	LLY	Adaptive volatility	49.31	33.81	94.1	191.38	10/17

We then scored the full forecast distributions and found a ticker-dependent benefit from the adaptive-volatility model (Table 4). In 2025, LLY’s five-session CRPS fell from 29.60 under JumpHMM to 28.57 under the adaptive-volatility model, while central 90% coverage increased from 69.9% to 84.4%. Average interval width grew from \$100.40 to \$151.37, so the coverage gain came with a wider range of predicted prices. The lower CRPS showed that this trade improved the distribution score, although coverage stayed below its nominal level. In 2026, LLY changed in the same direction, with CRPS falling from 35.60 to 33.81 and coverage rising from 70.6% to 94.1%. The adaptive-volatility model had lower date-level CRPS on 131 of 245 LLY origins in 2025 and on ten of seventeen in 2026 (Table 4). For GS, however, CRPS rose slightly in 2025, from 16.22 to 16.32, and by 20% in 2026, from 13.03 to 15.58. Both GS models covered every 2026 endpoint, but the adaptive-volatility intervals were wider. Mean-based RMSE also stayed close to the unchanged-price benchmark (Supplementary Table S31). One-session forecasts likewise showed little separation in central price error from an unchanged-price forecast (Supplementary Table S32). The adaptive-volatility model therefore improved the range of LLY’s forecasts, while its median forecasts stayed close to an unchanged price.

Finally, we widened the emission cutoff from $b = 10$ to $b = 20$, repeated the scenario, ablation, forecast, and stock-benchmark simulations, and observed small changes in the loss and forecast summaries (Supplementary Tables S34 and S35). Across all fitted states, each cutoff implied daily return limits for each stock (Supplementary Table S33). In the fitted illustrations, the wider cutoff changed mean short-call P&L at expiration by less than \$0.02 per share and its 5% expected shortfall by less than \$0.07. At the ablation’s ten-day endpoint for the coupled factor, it changed mean call P&L by less than \$0.004 and expected shortfall by less than \$0.02 (Supplementary Table S34). In the forecast comparisons, five-session coupled-factor option MAE changed by less than \$0.007 per share and the reported stock CRPS values by less than \$0.002 (Supplementary Table S35). The wider cutoff therefore did not change the conclusion of any forecast comparison.

4 Discussion

In this study, we developed a framework for examining how IV assumptions affect American-option values while keeping a chosen stock-return model, here JumpHMM, fixed. We repriced identical stock paths under five ways of setting IV. These held IV fixed at its starting value (frozen IV), set it each day to the fitted surface’s prediction, moved it partway toward that prediction each day, added random shocks to that movement, or linked those shocks to stock returns. The choice changed option values before expiration and the outcome of closing short positions early. Starting values and payoffs at expiration agreed exactly, so the experiment was a controlled comparison of the IV assumptions. The pattern of those changes followed from how each option’s implied variance

was updated in (12). With $\kappa = 15$ and daily steps, each trading day closed about 6% of the gap between an option's implied variance and the variance predicted by the fitted surface. Half of any gap therefore remained after about eleven trading days. The version without random shocks lagged behind the moving surface prediction as a result. After ten trading days, its P&L differences from setting IV each day directly to the surface prediction were at least three quarters as large as those of frozen IV (Supplementary Table S13). The random shocks averaged zero. For the GS put, adding them raised the average absolute price difference from prices with IV set directly to the surface prediction from \$0.42 to \$1.75, while the average P&L difference changed by \$0.06. Price changes on individual paths were therefore large, but they canceled across paths and left average P&L nearly unchanged. Linking the shocks to stock returns with a negative coefficient raised IV after the stock fell and lowered it after the stock rose. Stock volatility tends to move the same way, rising after prices fall, a pattern known as the leverage effect Cont [2001]. This link raised put values on falling-stock paths, where short puts already lost money. It lowered call values on rising-stock paths, where short calls lost money. For both GS and LLY, it therefore increased the average loss in the worst 5% of outcomes (expected shortfall) for short puts and reduced it for short calls.

The forecast tests asked a separate question, whether the model predicted later market prices. With its parameters held fixed, the full IV update reduced the error of the average option forecast only slightly relative to frozen IV (Table 3). The advantage was not consistent across dates or when forecasts were summarized by the median instead of the mean (Table 3; Supplementary Table S25). The update's central 90% price ranges contained every observed GS price but only about two thirds of LLY prices. The slow adjustment also limited what the IV update could add over five trading days. Every version started from the IV observed on the forecast date. Each option's surface prediction was rescaled to equal that IV on that date, so gaps opened only as stock moves and the passage of time changed the prediction. The update closed only about a quarter of any such gap in five days. The changing prediction and the random shocks also raised IV on some paths and lowered it on others. Averaged across paths, the updated IV therefore stayed within 0.3 volatility points of its starting value, although individual paths moved about 2.5 points (Supplementary Table S27). Frozen IV kept the starting value throughout, so the two average option forecasts stayed close. An update with fixed parameters that pulls IV toward a fixed surface carries no information about future IV beyond how the surface prediction changes with moneyness and time to expiration. Observed IV surfaces, by contrast, shift over time. Index-option surfaces, for example, move in level, skew, and curvature Cont and da Fonseca [2002]. A better forecast would likely need an input that tracked the IV level. The simulator's contribution was to compare these IV assumptions on the same options, stock paths, and pricing calculation. Whether any of them matched the market was a separate question, which only the comparisons with later option and stock prices could answer.

Those comparisons pointed to the stock forecast. Repeating the option forecasts with the stock paths that actually occurred cut option errors 3.8- to 5.4-fold on the same options and dates (Supplementary Table S22), so the stock forecast was the main source of option forecast error. The median stock forecasts from JumpHMM nearly matched a forecast of no price change because of its drift (Table 4). We imposed an average log return of 10% a year on JumpHMM, about 0.2% over five trading days. The simulated five-day log return had a standard deviation near 4%, about twenty times larger. The median simulated price therefore rose by an average of only 0.16–0.27% from the starting price (Supplementary Table S27), so its errors nearly matched those of the no-change forecast. Expected returns are small relative to short-horizon return variation, and even a constant expected return can be estimated precisely only from long spans of data Merton [1980]. Regressions that predict the stock market's excess return have also rarely beaten its historical average out of sample Welch and Goyal [2008]. Our direction-predicting model, which forecast drift from recent stock and market returns, behaved the same way. It forecast 2019–2024 prices best with its drift set to zero (Supplementary Table S30). Starting JumpHMM in the hidden state implied by recent returns did not materially improve five-day forecasts either (Supplementary Table S29). The model's switching between states erased the influence of the starting state within a few days.

The adaptive-volatility model, which scaled its forecast ranges by recent volatility, helped LLY but not GS (Table 4). Volatility, unlike direction, persists enough to be forecast from recent returns Cont [2001], Andersen and Bollerslev [1998], and LLY's volatility stayed above JumpHMM's level in both test periods. Each JumpHMM forecast started from the model's long-run state probabilities, so the width of its forecasts stayed at the volatility of its 2014–2024 fit. The standard deviation of LLY's daily returns was 1.5 times that level in 2025 and 1.3 times in August and September

2026 (Supplementary Table S27). It estimated volatility as an exponentially weighted moving average (EWMA) of recent squared returns. This estimate tracked those levels and widened LLY’s forecast ranges toward the observed spread of outcomes. The wider ranges improved LLY’s continuous ranked probability score (CRPS) in both periods. The CRPS rewards forecast distributions concentrated near the observed outcome. Even so, the adaptive-volatility model’s 90% ranges still contained fewer than 90% of the 2025 outcomes (Table 4). In 2025, GS’s daily volatility was within 10% of the JumpHMM level, so adapting it changed the score little (Supplementary Table S27). In August and September 2026, the standard deviation of GS’s daily returns was 1.40% (Supplementary Table S27). That was below both the 1.80% JumpHMM level and the adaptive-volatility estimate, which April–July returns had raised to an average of 2.26%. The 90% ranges of both models already contained every 2026 GS outcome (Table 4). The adaptive-volatility model’s wider ranges therefore made its forecasts less precise without making them more reliable, and CRPS penalizes that trade Gneiting et al. [2007]. The evidence therefore favors widening JumpHMM’s forecast ranges when a ticker’s recent volatility exceeds the model’s level. Neither the adaptive-volatility model nor the direction-predicting model forecast better on average, so we kept JumpHMM as the example stock model and reported both as comparisons.

Two further problems lie outside what the forecast comparisons can test. The binomial tree prices each option on its own, so nothing forces prices to be consistent across strikes. Some GS prices violated no-arbitrage conditions across strikes, even when IV was set directly from the fitted surface (Supplementary Table S15). For a strategy that holds several options, those inconsistencies matter because decisions depend on relative prices as well as the value of each position. Methods that simulate IV surfaces under no-arbitrage constraints offer a starting point Cont and Vuletić [2023]. Those constraints apply to European options, so American prices from the tree would still need their own checks before simulated prices replace market data. Fitting the surfaces posed a second problem. The neural surfaces fitted IV more closely than the parametric surface across all observations (Table 1). Yet on May 11, one of the dates used for fitting, they overpredicted near-the-money IV for MSFT and LLY. The surface fitted on 68 trading days through July 31 showed a related error on later dates. Daily errors showed that LLY’s overprediction on later dates began after a scheduled earnings report. The surface fitted through July underpredicted LLY’s IV by 17.90 volatility points on August 4, the trading day before the August 5 report. It then overpredicted LLY’s IV by 2.04 to 8.07 points on every observed day from August 6 through September 4 (Supplementary Table S27). Option prices have long shown this pattern, with IV rising before an anticipated announcement and falling after it Patell and Wolfson [1979], Dubinsky et al. [2019]. Each ticker’s fitted IV level averaged over the fitting period, so it could not represent IV both before and after a report. For GS, the July 14 report lay inside the fitting period, and the next report came after the test period. Its daily errors on later dates ranged from 3.07 points below to 3.59 points above observed IV. Averaged over the five observed sessions before and after each ticker’s latest report, the surface’s error shifted by 3.36 points for GS, compared with 16.45 points for LLY (Supplementary Table S27). The May 11 errors fit the same explanation. The two tickers whose IV the surfaces overpredicted, MSFT and LLY, reported on April 29 and April 30, after ten of the fifteen fitting days (Supplementary Table S5). Adding the time to scheduled earnings reports as a surface input reduced error when surfaces fitted on earlier April dates were tested on April 23 and 24 (Table 2). Refitting the July surfaces with the same inputs cut LLY’s overprediction after its report from 6.17 to 3.85 points, with both values averaged across three training seeds (Supplementary Table S28). That reduction fell short of the halving we had set in advance as support. Report timing therefore explained part of LLY’s error but not all of it. The remainder is consistent with each sector network sharing one earnings response among tickers whose IV moved by different amounts around their reports. In the forecast tests, rescaling the surface to the IV observed on each forecast date removed the starting level error but left the inconsistencies across strikes in place. Pricing each option with the IV that Alpaca, the data vendor, reported on the forecast’s end date reduced errors further, although it used information from that later date (Supplementary Table S24). Accurate IV surfaces, accurate stock forecasts, accurate option prices, and prices consistent across strikes are therefore separate requirements, and a synthetic option market needs all four.

The data were the main limitation. All option quotes came from Alpaca’s free indicative feed, which is derived from exchange quotes. Our price errors therefore measured agreement with Alpaca’s quotes, not with prices at which trades could execute, and the download times did not tie stock and option prices to the same moment. The observation windows were also short. The surface comparisons used fifteen daily snapshots, the later-date tests trained each network with one random

seed, and the option forecasts covered 23 trading days. Overlapping forecast periods and shared market moves further reduced the independent information in these tests. The collection kept only some expiration ranges each day, so the one-month options we first selected had no quotes five trading days later (Supplementary Table S20). The shorter-dated options that replaced them could not validate the one-month examples. Several conclusions also rest on thin evidence. We proposed the adaptive-volatility and direction-predicting models after seeing the August and September misses. The earnings explanation rested on a few reports for three tickers. We also did not check the cap on JumpHMM’s daily returns against the largest real stock moves. The IV update’s parameters stayed fixed, and the two extensions that would tie the IV level to JumpHMM’s hidden state and its tail visits stayed switched off. The present results therefore support controlled comparisons of IV assumptions and the specific forecasts reported here, not trading use. Complete daily histories of the same options, collected across different market conditions, would allow the forecast tests to be repeated on one-month options and the switched-off extensions to be tested.

5 Conclusion

In this study, we built a simulator that values American options along stock paths from a separately chosen stock model, here the jump hidden Markov model JumpHMM. It updated each option’s IV on every simulated date. Each option’s implied variance moved partway each day toward the prediction of a neural surface fitted to past quotes. This update borrowed the mean-reverting form of the Heston model’s variance equation and added random shocks. A binomial tree then converted the resulting IV into the option’s price. More flexible surfaces, fitted separately to smaller groups of tickers, matched the fitting data more closely, but their accuracy on later dates was uneven. Repricing identical stock paths under different IV updates changed option values before expiration and the outcome of closing positions early, while payoffs at expiration stayed the same. In forecasts of later option prices, the IV update with random shocks linked to stock returns showed no consistent advantage over holding IV fixed. Repeating the forecasts with the stock paths that actually occurred reduced option errors, which pointed to the stock forecast as the main source of error. In stock forecasts for 2025 and for August and September 2026, JumpHMM, an adaptive-volatility model, and a direction-predicting model all predicted prices about as accurately as assuming no change. The adaptive-volatility model improved the predicted range of stock prices for LLY in both periods but not for GS. Tuning on 2019–2024 data found no benefit from predicting direction with recent stock and market returns. The direction-predicting model therefore gave the same forecasts as the adaptive-volatility model. The simulator therefore supports reproducible comparisons of IV and stock assumptions, but it did not forecast better than simpler alternatives. Saved observations, fitted models, simulation outputs, and scoring code make every comparison reviewable. With complete option histories and prices made consistent across strikes, the same approach could supply realistic option prices for testing trading and hedging systems on market paths that never happened.

A Interpretation of the IV Factor

A continuous-time square-root process motivated the Euler update in (12). For a fixed target, the process is given by:

$$dv_{a,t} = \kappa(\bar{v}_{a,t} - v_{a,t}) dt + \sigma_v \sqrt{v_{a,t}} dW_{a,t}. \quad (18)$$

where contract a indexes ticker, strike, and expiration, and the target $\bar{v}_{a,t}$ from (7) changes with current moneyness and calendar DTE. With a fixed target, the stationary mean of this process, when it exists, equals $\bar{v}_a$. In the simulation, the target moved every trading day and the floor in (12) modified the process. The stationary mean therefore explains why each factor reverts toward its target, but it does not give the simulated distribution.

B Calibration Details

Snapshot labels, capture timestamps, and underlying-session dates did not always coincide (Table S1). All dates are in 2026. The May 11 underlying-session snapshot was captured on May 12. The first snapshot contained 23 tickers and the remaining snapshots contained 31. The [source repository](#) provides the experiment drivers and reproduction instructions. Its data manifest records each file’s SHA-256 hash and filtered row count. The saved ablation outputs include the pilot constants, path-level prices, numerical checks, and copies of the source code, so each reported comparison can be traced to its inputs.

Table S1: Dates of the calibration snapshots. The April earnings holdout split dates by snapshot label, and the May 11 single-date holdout used the underlying-session date. The first snapshot is labeled April 14, but its underlying close was from April 13.

Snapshot label	Capture date	Underlying session	Rows
04-14-2026	2026-04-14	2026-04-13	18,250
04-15-2026	2026-04-15	2026-04-15	17,711
04-16-2026	2026-04-16	2026-04-16	18,344
04-17-2026	2026-04-17	2026-04-17	17,281
04-21-2026	2026-04-21	2026-04-21	16,760
04-22-2026	2026-04-22	2026-04-22	15,551
04-23-2026	2026-04-24	2026-04-23	11,482
04-24-2026	2026-04-24	2026-04-24	15,351

05-08-2026	2026-05-08	2026-05-08	12,293
05-11-2026	2026-05-12	2026-05-11	14,442

Table S2: Sector assignment of the 31 tickers across the fifteen snapshots. Counts are the filtered observations used in fitting.

Sector	Observations	Tickers
ETF	102,738	IWM, QQQ, SPY
Technology	68,334	AAPL, AMD, AVGO, GOOG, INTC, META, MSFT, MU, NVDA, QCOM
Healthcare	26,387	ABBV, AMGN, BMY, JNJ, LLY, MRNA, PFE, UNH
Financials	17,938	BAC, GS, JPM, WFC
Retail	11,320	TGT, UPS, WMT
Energy	7,832	CVX, OXY, XOM

Table S3: In-sample RMSE by sector, in volatility percentage points. The sector network improved on the global neural network in every group. Technology and healthcare kept the largest errors.

Sector	Parametric	Global NN	Sector NN	Observations
ETF	10.54	8.69	6.10	102,738
Financials	9.05	7.79	6.70	17,938
Energy	9.36	8.24	7.88	7,832
Retail	11.73	10.23	9.50	11,320
Healthcare	13.49	12.71	12.53	26,387
Technology	15.58	15.31	14.47	68,334

Table S4: Per-ticker in-sample RMSE for the 29 qualified tickers, sorted by the reduction relative to the sector network. A positive reduction means the ticker's own network fitted better than its sector network. The final rows count the tickers that improved and worsened. Combining per-ticker networks with sector fallbacks reduced pooled RMSE from 10.24 to 9.73 volatility percentage points (Table 1). Two tickers, BMY and PFE, kept their sector surfaces.

Ticker	Observations	Sector NN	Per-ticker NN	Reduction
JNJ	2,190	11.14	7.17	3.97
MRNA	2,851	17.49	13.74	3.76
AAPL	6,594	14.30	12.59	1.70

JPM	3,720	6.18	6.65	-0.47
Tickers with lower per-ticker RMSE				21
Tickers with higher per-ticker RMSE				8

Table S5: Mean IV near the money in the May 11 smile panels (Fig. 1). Each row uses the plotted calls and puts with $0.98 \leq K/S \leq 1.02$ at the indicated calendar days to expiry (DTE). Observed and predicted IV are percentages. Bias is the mean per-ticker predicted IV minus observed IV, in percentage points. Predictions use the saved fifteen-date fit evaluated at each observed contract. The NVDA subset contains only two observations. The public earnings calendar dated GS, MSFT, and LLY reports on April 13, April 29, and April 30, 2026, within the calibration window.

Ticker	DTE	N	Observed IV	Predicted IV	Bias
SPY	7	52	13.57	13.75	+0.18
NVDA	7	2	38.65	34.02	-4.62
MSFT	9	14	28.47	37.92	+9.45
LLY	11	20	38.59	46.49	+7.90
GS	11	24	32.06	31.74	-0.32
AVGO	9	14	49.08	43.72	-5.37

Table S6: May 11 price-error summary for the contracts plotted in Fig. 2. Dollar values are medians across the plotted contracts, and errors are absolute differences between the tree price and the market mid. Inside spread is the share of contracts whose absolute per-ticker error was at most their half-spread. The per-ticker column used a per-ticker surface where qualified and a sector surface otherwise. The market-IV reference passed each contract’s reported IV to the same 200-step CRR tree.

Ticker	DTE	N	Median half-spread	Median per-ticker error	Inside spread	Median market-IV error
SPY	7	176	\$0.03	\$0.12	33%	\$0.01
NVDA	7	34	\$0.04	\$0.13	35%	\$0.12
LLY	11	156	\$2.98	\$4.01	30%	\$0.67
GS	11	145	\$1.56	\$0.46	88%	\$0.12

Table S7: Best and worst ticker-level in-sample RMSE under the sector networks. Errors are in volatility percentage points.

Rank	Ticker	Observations	RMSE	Sector
<i>Best five</i>				
1	GS	8,772	5.40	Financials
2	SPY	42,224	6.02	ETF
3	IWM	21,368	6.11	ETF
4	QQQ	39,146	6.17	ETF
5	JPM	3,720	6.18	Financials
<i>Worst five</i>				
27	PFE	1,300	17.66	Healthcare
28	AMD	4,566	17.74	Technology
29	INTC	3,417	17.78	Technology
30	MU	6,619	18.45	Technology
31	QCOM	3,375	21.46	Technology

B.1 Single-date holdout

To test transfer to a nearby date, we held out May 11, 2026, and retrained the sector surfaces on the other fourteen dates, standardizing inputs with the training rows alone. Pooled test error exceeded training error by 0.68 volatility percentage points (Table S8). Energy and retail had larger gaps, so the small pooled gap hid poorer transfer in those sectors. The test used one held-out date and one training seed.

Table S8: Sector-network RMSE after fitting on fourteen dates and holding out the 14,442 observations from May 11, 2026. Values and test-minus-train gaps are in volatility percentage points.

Sector	Train	Test	Gap
ETF	6.12	5.87	−0.25
Financials	6.72	6.32	−0.40
Healthcare	12.58	12.00	−0.58
Technology	14.45	15.04	+0.58
Energy	7.74	9.97	+2.23
Retail	9.21	13.17	+3.96
Pooled	10.21	10.89	+0.68

C Earnings-Holdout Ticker Results

We broke the April earnings-holdout result down by technology ticker, with the same training and test observations for the two-input and four-input models (Table S9). Several tickers with a peer earnings date near the holdout had lower error with the earnings inputs, but AVGO, NVDA, and INTC had higher errors. The ticker and peer distances entered together, so the comparison could not separate their contributions. Calendar distance also carries no information about the sign or size of an earnings surprise.

Table S9: Technology-ticker test RMSE for the pooled model (A) and earnings-aware model (C). Inputs e and e^{peer} are median signed ticker distance and minimum peer distance, in days. Error differences are in volatility percentage points.

Ticker	e	e^{peer}	A: pooled	C: event inputs	Difference
QCOM	+5	1	41.66	37.59	−4.07
AMD	+11	1	40.07	36.50	−3.57
META	+5	1	14.32	10.73	−3.59
MSFT	+5	1	14.00	10.73	−3.28
GOOG	+5	1	9.87	7.90	−1.97
MU	−30	1	16.95	15.59	−1.36
AAPL	+6	1	10.42	10.34	−0.08
AVGO	+30	1	12.58	12.83	+0.24
NVDA	+26	1	9.43	10.47	+1.05
INTC	−1	5	33.17	35.94	+2.77

D Scenario Statistics and Greeks

The GS and LLY illustrations shared one simulation design (Table S10). For GS, the seller usually kept the full premium but faced large losses in the lower tail (Table S11). The premium-retained interval is a two-sided 95% Wilson interval for the fraction of paths that expired out of the money. It measures only the Monte Carlo sampling error in that fraction.

Table S10: Simulation settings shared by the GS and LLY illustrations.

Setting	Value
Simulation paths	1,000
Random seed	20260429
Horizon	April 28–May 29, 2026
Calendar days	31
Trading transitions	22
Annual mean-growth prior	10%
Mean-reversion rate κ	15
Factor volatility σ_v	0.5
Return–factor coupling ρ	−0.6
Risk-free rate r	4.25%
Dividend yield q	0
Leisen–Reimer depth	201

Table S11: Scenario results for GS from 1,000 paths between April 28 and May 29, 2026. The horizon had 31 calendar days and 22 trading-day steps. Option values and P&L are in dollars per share.

Statistic	Short put	Short call
Initial spot	926.38	
Strike	890.00	970.00
Market delta	−0.295	+0.328
Market IV	31.2%	28.9%
Market mid	16.51	16.09
Model entry value	17.26	16.07
Model value minus market mid	0.75	−0.02
Mean P&L	4.30	−2.19
Monte Carlo SE of mean	0.89	1.23
Median P&L	16.51	16.09
Standard deviation	28.01	38.87
5% quantile	−58.96	−86.18
5% expected shortfall	−92.15	−130.77
Premium retained	74.0%	67.7%
Wilson 95% interval	71.2–76.6%	64.7–70.5%
Delta-heuristic premium retained	70.5%	67.2%
Simulated minus heuristic	+3.5 pp	+0.5 pp

We calculated Greeks along each path by central finite differences on the same Leisen–Reimer tree that supplied the base price (Algorithm S1). On the GS paths, delta approached ± 1 on paths heading toward exercise, gamma concentrated near the strike, and Vega declined toward zero (Fig. S1). The figures use the long-option sign convention, so a short position’s Greeks have the opposite sign.

Algorithm S1 Greeks by central finite differences along each path

Require: State (S, σ, τ) with calendar DTE τ ; contract (K, r) ; LR tree steps N_{LR} ; relative spot bump h_S ; absolute IV bump h_σ .

Ensure: Δ , Γ , and Vega.

- 1: $T_{\text{yr}} \leftarrow \tau/365$.
 - 2: $P_+^S \leftarrow \text{LR}(S(1+h_S), K, \sigma, T_{\text{yr}}, r)$ and $P_-^S \leftarrow \text{LR}(S(1-h_S), K, \sigma, T_{\text{yr}}, r)$.
 - 3: $P_0^S \leftarrow \text{LR}(S, K, \sigma, T_{\text{yr}}, r)$.
 - 4: $P_+^\sigma \leftarrow \text{LR}(S, K, \sigma+h_\sigma, T_{\text{yr}}, r)$ and $P_-^\sigma \leftarrow \text{LR}(S, K, \sigma-h_\sigma, T_{\text{yr}}, r)$.
 - 5: $\Delta \leftarrow (P_+^S - P_-^S)/(2h_S S)$.
 - 6: $\Gamma \leftarrow (P_+^S - 2P_0^S + P_-^S)/(h_S S)^2$.
 - 7: $\text{Vega} \leftarrow 0.01(P_+^\sigma - P_-^\sigma)/(2h_\sigma)$.
 - 8: **return** $(\Delta, \Gamma, \text{Vega})$.
-

Figure S1: Simulated evolution of GS long-option delta, gamma, and Vega along the stock paths. Sensitivities come from the 201-step Leisen–Reimer tree, with stock-price bumps of 1.5% and IV bumps of 0.005. Vega is in dollars per volatility percentage point.

Table S12: Scenario results for LLY from 1,000 paths between April 28 and May 29, 2026. The horizon had 31 calendar days and 22 trading-day steps. Option values and P&L are in dollars per share.

Statistic	Short put	Short call
Initial spot	873.83	
Strike	825.00	940.00
Market delta	-0.303	+0.309
Market IV	44.4%	44.0%
Market mid	23.30	20.76
Model entry value	21.95	18.96
Model value minus market mid	-1.35	-1.80
Mean P&L	16.39	10.61
Monte Carlo SE of mean	0.63	0.91
Median P&L	23.30	20.76
Standard deviation	19.86	28.66
5% quantile	-27.91	-51.96
5% expected shortfall	-56.84	-94.18
Premium retained	80.7%	79.3%
Wilson 95% interval	78.1–83.0%	76.7–81.7%
Delta-heuristic premium retained	69.7%	69.1%
Simulated minus heuristic	+11.0 pp	+10.2 pp

Figure S2: Simulated evolution of LLY stock prices (a), put values (b), and call values (c) along 1,000 paths between April 28 and May 29, 2026. The fitted surfaces included observations from this period, so these paths illustrate the model and are not an out-of-sample forecast. Time is measured in calendar days from April 28. Black curves show pointwise medians, and shading contains the middle 90% of values. Red and blue curves show group medians for the 1st–5th and 95th–99th terminal-stock percentiles. Option values are in dollars per share and equal the cost of buying back the option for a short seller. Entry premiums were \$23.30 per share for the put and \$20.76 for the call (Supplementary Table S12).

Figure S3: Simulated evolution of annualized IV at the LLY put strike (a) and call strike (b). Both panels express IV as percentages on the same vertical scale. Curves show pointwise medians across all 1,000 paths and within the terminal-stock groups in Supplementary Fig. S2. Shading shows the 5th–95th percentile band. Time is measured in calendar days from April 28, 2026, and stops before expiration because the payoff at expiration does not depend on IV.

Figure S4: Simulated evolution of LLY long-option delta, gamma, and Vega along the stock paths. Sensitivities come from the 201-step Leisen–Reimer tree. Short-position Greeks have the opposite sign.

E IV Ablation and Strike Audit

At the primary endpoint, ten trading days after entry, we compared the P&L from closing each short position under the five IV variants on shared stock paths (Table S13). The three evaluation seeds repeat the comparison with the same fitted models and pilot constants (Table S14). The paired standard errors apply to mean differences only, so the table gives no interval for expected shortfall.

Table S13: Profit and loss from closing short positions after ten trading days (May 12, 2026), with 17 calendar DTE remaining. Each row uses 3,000 paths, and monetary values are in dollars per share. $\Delta P\&L$ and mean $|\Delta P|$ compare each variant with the direct surface on identical paths. Parentheses give the paired Monte Carlo standard error of mean $\Delta P\&L$. A more negative 5% expected shortfall means larger losses in the lower tail.

Contract	IV variant	Mean P&L	ES _{5%}	$\Delta P\&L$ (SE)	Mean $ \Delta P $
GS put	Frozen IV	0.67	-63.08	+0.28 (0.01)	0.51
GS put	Direct surface	0.39	-62.59	+0.00 (0.00)	0.00
GS put	Mean reversion	0.64	-62.95	+0.25 (0.01)	0.42
GS put	Noise, $\rho = 0$	0.70	-62.98	+0.31 (0.04)	1.75
GS put	Full factor	0.34	-64.60	-0.05 (0.04)	1.77
GS call	Frozen IV	-0.03	-71.07	+0.87 (0.01)	0.87

GS call	Mean reversion	-0.21	-71.42	+0.69 (0.01)	0.69
GS call	Noise, $\rho = 0$	-0.12	-71.53	+0.77 (0.04)	1.93
GS call	Full factor	0.19	-69.82	+1.09 (0.04)	1.96
LLY put	Frozen IV	7.15	-35.54	+1.33 (0.01)	1.33
LLY put	Direct surface	5.83	-36.17	+0.00 (0.00)	0.00
LLY put	Mean reversion	6.96	-35.53	+1.13 (0.01)	1.13
LLY put	Noise, $\rho = 0$	7.01	-35.70	+1.18 (0.04)	2.04
LLY put	Full factor	6.66	-38.27	+0.83 (0.04)	1.96
LLY call	Frozen IV	6.31	-47.30	+2.23 (0.01)	2.23
LLY call	Direct surface	4.08	-50.42	+0.00 (0.00)	0.00
LLY call	Mean reversion	5.90	-47.95	+1.82 (0.00)	1.82
LLY call	Noise, $\rho = 0$	5.95	-48.48	+1.87 (0.04)	2.36
LLY call	Full factor	6.26	-45.18	+2.18 (0.04)	2.41

Table S14: Full factor versus direct surface after ten trading days, with numerical diagnostics, by evaluation seed. Each row uses 1,000 paths, and monetary values are in dollars per share. Mean $|\Delta P|$, mean $\Delta P\&L$, and its paired standard error compare the full factor with the direct surface. Outside is the percentage of path dates before expiration on which strike/spot lay outside the 0.8 to 1.2 range of the calibration data. Floor is the largest percentage of simulated dates, across the five IV variants, on which the factor sat at the variance floor. Tree change is the largest absolute price change from 201 to 401 tree steps, across the five variants, on the first twenty paths after ten and twenty trading days.

Contract	Seed	Mean $ \Delta P $	Mean $\Delta P\&L$	Paired SE	Outside (%)	Floor (%)	Tree change (\$)
GS put	20260429	1.82	-0.08	0.07	0.7	0.0	0.0013

LLY call	20260431	2.37	+2.12	0.07	2.6	0.0	0.0000

The strike audit checked necessary conditions for consistent prices across strikes at 401 tree steps (Table S15). The grid had eleven fixed strikes at the scenario expiration, evaluated at entry and on fifty stock paths after ten and twenty trading days. As the stock moved, some strikes left the moneyness range of the calibration data, so the audit included extrapolated surface values. Each variant and ticker supplied 2,222 bound checks, 2,020 adjacent-strike checks, and 1,818 convexity checks across calls and puts. Violation counts were identical at 201 and 401 steps (Table S16). The saved output lists each test location and violation size.

Table S15: Strike-condition violations exceeding \$0.01 per share at 401 tree steps. Entries show violations/tests. Vertical denotes the upper bound on an adjacent-strike option-price difference. Max reports the largest positive deviation across the four checks, including deviations below the reporting tolerance.

Ticker	Variant	Bounds	Monotonicity	Vertical	Convexity	Max (\$)
GS	Frozen IV	0/2222	0/2020	0/2020	0/1818	0.008
GS	Direct surface	0/2222	68/2020	68/2020	178/1818	0.113
GS	Mean reversion	0/2222	2/2020	0/2020	0/1818	0.014
GS	Noise, $\rho = 0$	0/2222	3/2020	0/2020	0/1818	0.014
GS	Full factor	0/2222	3/2020	0/2020	0/1818	0.013
LLY	Frozen IV	0/2222	0/2020	0/2020	0/1818	0.000

F Details of the Tests on Later Dates

Fold errors for the 53 expanding-window splits are summarized by test month (Table S17). The July-cutoff surfaces used a longer training window, the capture audit, recomputed calendar DTE, and a later test period, so their errors are reported separately (Table S18).

Table S17: Sector-surface prediction errors across the 53 expanding-window folds. Each fold fitted earlier capture dates and evaluated the next captured date using its observed stock price. The RMSE is in IV percentage points. The last row pools all 53 folds.

Test month	Folds	Median RMSE	Minimum	Maximum
April	6	12.72	7.79	17.45
May	17	9.62	8.65	11.30
June	18	10.02	8.55	19.25
July	12	9.76	7.68	10.51
All folds	53	9.92	7.68	19.25

Table S18: Training and held-out IV errors for sector surfaces fitted through July 31. Training used 68 underlying sessions, and testing used 23 later sessions from August 4 through September 4. Each RMSE pools observations within the indicated group. Bias is predicted minus observed IV, in percentage points. The last two rows show GS and LLY alone.

Group	Train rows	Test rows	Train RMSE	Test RMSE	Test bias
ETF	503,487	186,987	7.03	6.59	+3.08
Financials	83,005	27,853	7.40	7.81	+2.50
Energy	34,817	10,956	8.15	9.40	+2.45
Retail	50,776	15,096	10.02	11.77	+1.83
Healthcare	126,818	45,472	12.14	12.21	+3.77
Tech	374,635	138,697	14.70	22.91	+14.81
Pooled	1,173,538	425,061	10.79	14.75	+6.88
GS	41,119	14,330	6.78	6.30	+0.88
LLY	39,242	13,753	9.47	9.96	+4.61

Table S19: Data checks for the expanding-window and July-cutoff experiments. The expanding-window rows come from an independent reconstruction of the saved row counts. The July-cutoff rows come from the capture audit. Every excluded file had a retained file for the same ticker and session.

Experiment	Check	Value
Expanding-window folds	Capture dates	58
	Option files	1,790
	Accepted observations	986,492
	Crossed or missing asks	0
	Missing or nonpositive bid or ask sizes	0
July-cutoff surfaces	Downloaded files	2,833
	Files retrieved during trading hours (excluded)	20
	Superseded files (excluded)	0
	Files retained	2,813
	Training observations (68 sessions)	1,173,538
	Test observations (23 sessions)	425,061

Options were chosen at each origin before any later quote was examined. The availability counts separate forecasts whose endpoint fell inside the test window from those with an exact-symbol quote at the endpoint (Table S20). The observed-stock diagnostic also needed a recorded close on every intervening session, which is stricter than having an endpoint quote. It therefore used a smaller subset, the same for every IV variant.

Table S20: Availability of exact-contract outcomes by cohort, ticker, and horizon. Selected counts include all origin-selected contracts whose endpoint fell within the fixed window, including endpoints on missing capture dates. Full stock path counts selected contracts with all intervening stock observations, whether or not the endpoint option quote was available. Horizons are in trading sessions.

Cohort	Ticker	Horizon	Origins	Selected	Matched	Missing	Full stock path
monthly	GS	1	22	44	34	10	42
monthly	GS	5	18	36	0	36	26
monthly	LLY	1	22	44	34	10	42
monthly	LLY	5	18	36	0	36	26
short	GS	1	22	44	42	2	42
short	GS	5	18	36	34	2	26
short	LLY	1	22	44	41	3	42
short	LLY	5	18	36	30	6	26

Table S21: One-session option forecasts for the monthly cohort. Scores first average matched contracts within each ticker and origin and then average dates. Monetary quantities (MAE, CRPS, and central 90% interval width) are in dollars per share. Coverage averages the within-origin fraction of observed midpoints inside that interval across dates.

Ticker	IV variant	Dates	Quotes	MAE	CRPS	Coverage (%)	Width
GS	Frozen IV	17	34	3.80	2.65	85.3	15.15
GS	Direct surface	17	34	3.79	2.66	82.4	14.68
GS	Mean reversion	17	34	3.80	2.65	85.3	15.15
GS	Uncoupled factor	17	34	3.80	2.65	88.2	16.05
GS	Coupled factor	17	34	3.79	2.65	94.1	15.64
LLY	Frozen IV	17	34	6.11	4.52	76.5	17.32
LLY	Direct surface	17	34	6.16	4.52	76.5	17.55
LLY	Mean reversion	17	34	6.11	4.52	76.5	17.32
LLY	Uncoupled factor	17	34	6.11	4.48	73.5	18.24
LLY	Coupled factor	17	34	6.08	4.51	73.5	17.71

Table S22: Five-session diagnostic for the shorter-maturity cohort, with IV updated along the observed stock path. Because it uses the realized stock path, it is not a forecast. All variants use the same complete-path subset. Monetary quantities and aggregation follow Table 3. Simulated-path MAE scores the same origins and quotes with the simulated stock paths of the joint forecast. Comparing the two MAE columns shows how much of the error came from the stock forecast.

Ticker	IV variant	Dates	Quotes	MAE	CRPS	Coverage (%)	Width	Simulated-path MAE
GS	Frozen IV	13	26	1.07	1.07	0.0	0.00	4.67
GS	Direct surface	13	26	1.45	1.45	0.0	0.00	5.32
GS	Mean reversion	13	26	1.08	1.08	0.0	0.00	4.72
GS	Uncoupled factor	13	26	1.07	0.71	92.3	3.37	4.70
GS	Coupled factor	13	26	1.23	0.90	50.0	2.72	4.62
LLY	Frozen IV	13	24	1.74	1.74	0.0	0.00	10.66
LLY	Direct surface	13	24	2.25	2.25	0.0	0.00	10.72
LLY	Mean reversion	13	24	1.74	1.74	0.0	0.00	10.67
LLY	Uncoupled factor	13	24	1.73	1.35	84.6	4.40	10.66
LLY	Coupled factor	13	24	1.95	1.53	65.4	3.54	10.61

Table S23: Stock forecast scores at the observed endpoint dates for the original 1,000-path forecasts. The MAE scores forecast means. The random walk has zero log drift and the fixed pilot's one-session return standard deviation. Monetary errors are in dollars per share, and coverage refers to central 90% forecast intervals.

Ticker	Horizon	Stock model	Dates	MAE	CRPS	Coverage (%)
GS	1	JumpHMM	21	10.91	8.06	90.5
GS	1	Random walk	21	10.69	8.25	95.2
GS	5	JumpHMM	17	16.85	13.05	100.0
GS	5	Random walk	17	16.17	13.79	100.0
LLY	1	JumpHMM	21	19.26	14.80	71.4
LLY	1	Random walk	21	18.87	14.40	76.2
LLY	5	JumpHMM	17	49.83	35.71	70.6
LLY	5	Random walk	17	48.64	34.33	70.6

Table S24: American-tree prices computed with the IV reported at the endpoint, for matched options with valid reported IV. This diagnostic uses information from the endpoint, so it is not a forecast. The MAE is in dollars per share. Inside-spread frequencies compare each price with Alpaca's indicative bid and ask.

Cohort	Ticker	Horizon	Dates	Quotes	MAE	Inside spread (%)
monthly	GS	1	17	34	0.24	97.1
monthly	LLY	1	17	34	0.46	100.0
short	GS	1	21	42	0.16	100.0
short	GS	5	17	34	0.14	100.0
short	LLY	1	21	41	0.32	100.0
short	LLY	5	17	30	0.34	100.0

Table S25: Five-session option errors under mean and median point forecasts for the shorter-maturity cohort. Mean MAE and Mean RMSE score the simulated mean, and Median MAE scores the median. All errors are in dollars per share and use the same date-weighted options as Table 3. The prespecified comparison scores the mean, and the median is an added summary.

Stock	IV variant	Mean MAE	Median MAE	Mean RMSE
GS	Frozen IV	4.21	2.48	5.06
GS	Direct surface	4.86	2.62	5.62
GS	Mean reversion	4.26	2.50	5.10
GS	Uncoupled factor	4.24	2.48	5.08
GS	Coupled factor	4.19	2.48	4.99
LLY	Frozen IV	11.62	11.78	15.00
LLY	Direct surface	11.62	11.59	14.74
LLY	Mean reversion	11.62	11.77	14.98
LLY	Uncoupled factor	11.61	11.80	14.97
LLY	Coupled factor	11.59	11.79	14.92

Recomputing prices from the saved stock and variance paths reproduced the forecast means, quantiles, and CRPS. Increasing the tree from 201 to 401 steps changed sampled prices by at most \$0.0026 per share (Table S26). At the first origin for each ticker, the paired Monte Carlo standard errors of coupled-minus-frozen mean prices ranged from \$0.041 to \$0.061 across the four shorter-maturity options at five sessions (Table S26). These standard errors measure simulation precision for a single price difference, not variation across market dates. The small average MAE reductions therefore do not show that the coupled factor forecasts better (Table 3). In the observed-stock di-

agnostic, frozen IV, the direct surface, and deterministic mean reversion gave a single price once the stock path was fixed, so their central intervals had zero width. The stochastic factors' intervals reflected IV uncertainty alone, so their coverage measures something different from the coverage of the joint forecasts (Table S22). The saved score files include both cohorts, every horizon with outcomes, all five IV variants, and the date-level errors.

Table S26: Numerical checks of the forecast prices at the first origin, August 4, 2026. Sampled prices repeat the tree calculation with 201 and 401 steps for both cohorts, all five IV variants, calls and puts, and the first ten paths. Price changes and standard errors are in dollars per share. Paired Monte Carlo SE is the standard error of the mean coupled-minus-frozen price difference across 1,000 paths for the shorter-maturity options at the five-session endpoint.

Check	GS	LLY
Sampled prices, 201 and 401 steps	300	300
Largest price change, 201 to 401 steps	0.0022	0.0026
Paired Monte Carlo SE, five-session put	0.041	0.052
Paired Monte Carlo SE, five-session call	0.051	0.061

Several quantities explain the forecast outcomes (Table S27). With $\kappa = 15$ and $\Delta t = 1/252$, the Euler update in (12) retained a fraction $1 - \kappa\Delta t \approx 0.94$ of a factor's deterministic gap to a fixed target at each session. This gave a half-life of 11.3 sessions and closed 26.4% of the gap after five sessions and 45.9% after ten. The five-session rows used the seventeen scored origins per ticker and the matched contracts in Table 3. Their IV changes compared simulated IV five sessions after origin with the observed origin IV, averaging over paths and then contracts. The one-session volatility rows used the stock-benchmark origins in Table 4. Realized values were sample standard deviations of the observed one-session log returns, and EWMA values averaged the adaptive-volatility model's origin estimates. The GS EWMA estimate began from its 2014–2024 sample variance and rose through the April–July 2026 returns before the first August origin. The surface-bias rows break the held-out ticker bias in Table S18 down by underlying session. The report rows average each ticker's daily bias over the five observed sessions before and after its latest report, excluding the report day and weighting each session by its number of observations. They use training and held-out days alike. The public earnings calendar dated LLY's report on August 5, 2026, after the training cutoff, and GS's on July 14, 2026, inside the training window.

Table S27: Diagnostics of IV-factor persistence, central stock drift, stock volatility, and surface bias. Five-session rows average the scored short-maturity origins and matched options. Changes in IV are in volatility percentage points relative to the observed origin IV. One-session stock rows use the 2025 and August–September 2026 stock-benchmark origins. Surface bias is predicted minus observed IV for the July-cutoff sector surface, in volatility percentage points. Earnings reports fell on August 5, 2026, for LLY and July 14, 2026, for GS. Report rows exclude the report day.

Quantity	GS	LLY
<i>Five-session forecasts, short-maturity cohort</i>		
JumpHMM median price change (%)	0.27	0.16
JumpHMM log-return standard deviation (%)	3.98	3.76
Coupled mean IV minus origin IV (points)	0.30	0.18
Coupled mean absolute IV change (points)	2.49	2.47
Direct-surface mean absolute IV change (points)	5.50	4.12
<i>One-session stock return standard deviation (%)</i>		
JumpHMM pilot	1.80	1.70
Realized, 2025	1.97	2.57
EWMA at origin, 2025	1.94	2.52
Realized, August–September 2026	1.40	2.19
EWMA at origin, August–September 2026	2.26	2.14
<i>Held-out July-cutoff surface bias (points)</i>		
August 4	−3.07	−17.90
August 5	−0.96	−0.53
August 6–September 4, mean	1.20	6.17
August 6–September 4, range	−0.68 to 3.59	2.04 to 8.07
<i>Surface bias around each ticker’s latest report (points)</i>		
Five observed sessions before	−3.93	−11.26
Five observed sessions after	−0.57	5.19
Change	3.36	16.45

We tested the earnings explanation by refitting the July surfaces with the two earnings inputs used in the April holdout (Table S28). A protocol written before fitting kept the two-input surfaces’ training and test rows, architecture, and training schedule. It fitted seeds 42, 43, and 44 for both versions, with the underlying session as the observation date. The protocol called the explanation supported if the earnings inputs at least halved LLY’s mean absolute bias from August 6 through September 4, with every earnings-aware seed below every two-input seed. It called the explanation not supported if they did not reduce the bias. The earnings inputs reduced that bias from 6.17 to 3.85 volatility points on average, and every earnings-aware seed fell below every two-input seed. The 38% reduction fell short of half, so the prespecified verdict was partial. The inputs also reduced LLY’s underprediction on August 4 from 17.90 to 12.86 points and pooled held-out RMSE from 14.75 to 13.94 points, while GS’s held-out RMSE changed by less than 0.1 point. The two-input refits varied by less than 0.05 points across seeds in every reported quantity, so these differences exceed seed variation. Each sector network shares one earnings response across its tickers, so the refit could represent a typical report effect but not one sized to each ticker. Across their latest reports, LLY’s bias shifted about five times as much as GS’s (Table S27).

Table S28: Earnings-aware refit of the July-cutoff sector surfaces. Values are means across training seeds 42, 43, and 44, with the seed range in parentheses. Bias is predicted minus observed IV, and bias and RMSE are in volatility percentage points. Two-input seed 42 is the published surface. The earnings inputs are the signed calendar days to the ticker’s nearest report and the days to the nearest same-sector peer report, each clipped at 30. For ETFs, both inputs are the days to the nearest report among all non-ETF stocks.

Quantity	Two inputs	With earnings inputs
LLY bias, August 6–September 4	6.17 (6.16 to 6.18)	3.85 (3.54 to 4.05)
LLY bias, August 4	−17.90 (−17.92 to −17.88)	−12.86 (−13.04 to −12.73)
GS bias, August 6–September 4	1.21 (1.20 to 1.22)	0.51 (0.46 to 0.57)
LLY held-out RMSE	9.96 (9.96 to 9.97)	8.50 (8.36 to 8.59)
GS held-out RMSE	6.31 (6.30 to 6.31)	6.37 (6.31 to 6.41)
Pooled held-out RMSE	14.75 (14.75 to 14.76)	13.94 (13.87 to 14.00)
Pooled training RMSE	10.79 (10.78 to 10.79)	10.35 (10.29 to 10.39)

G Stock Forecast Evaluation

The saved GS and LLY models used daily steps of $1/252$ year and annualized excess log returns. Reconstructing the first-origin forecasts reproduced the saved stock means at both one and five sessions. In the initialization check, we inferred the current hidden state from the available daily returns and advanced it before generating the first future return. The inference tracked both the return state and the number of forced tail-state emissions left in a jump episode. Poisson durations kept all but at most 10^{-12} of the probability, with the remainder assigned to the final duration. A missing day advanced the hidden-state distribution without an observation likelihood. A return accumulated over several days was never treated as a daily observation. We removed the fixed pilot growth shift from observed annualized returns before computing likelihoods, to match the simulated observation model. We compared this conditional start with the original start on the same 2026 endpoints (Table S29). Both used three 10,000-path runs, with seeds separate from the four-method benchmark. The fitted transitions mixed the hidden states within a few sessions, so the conditional start had little effect on five-session central forecasts. Other exploratory checks, including a fixed 20-return volatility adjustment and Gaussian random walks, are kept in the saved experiment outputs.

Table S29: Stock forecast errors under original and history-conditioned initialization on identical 2026 endpoints. Each ticker has 21 one-session and 17 five-session origins. The MAE scores the forecast median. Errors are in dollars per share and average three 10,000-path runs. Filtered denotes initialization from available past returns, including inference of remaining jump duration.

Stock	Horizon	Original MAE	Filtered MAE	Original CRPS	Filtered CRPS
GS	1	10.64	10.79	7.99	8.44
GS	5	16.28	16.36	12.99	13.21
LLY	1	19.10	19.08	14.73	14.62
LLY	5	49.58	49.40	35.69	35.35

The benchmark comparison kept JumpHMM’s fitted parameters and truncated emissions and tested the adaptive-volatility and direction-predicting models against it. For each annual validation block from 2019 through 2024, regression training responses ended before the validation year and validation endpoints remained within it. The EWMA variance began with the sample variance of the first sixty training daily returns and then updated using only returns observed by each origin. Decay selection minimized $\frac{1}{2}[\log(ha_t) + y_{t,h}^2/(ha_t)]$, where $y_{t,h}$ was the observed cumulative log return over h sessions. We first averaged this loss within each ticker, validation year, and horizon, then gave the resulting groups equal weight. With the selected decay, the direction-predicting model’s regression fitted the next daily return divided by origin volatility. Its four features were the stock’s last daily return, its last five- and twenty-return sums, and SPY’s last five-return sum. Return sums were divided by the square root of the window length and by the same asset’s EWMA volatility at the origin, so

SPY’s feature used SPY’s volatility. Each feature column was then divided by its training root mean square. The ridge objective was the mean squared normalized one-session error plus the penalty times the squared coefficient norm, with no intercept. Penalty selection used $(y_{t,h} - h\hat{\mu}_t)^2/(ha_t)$, with the same group weighting as decay selection. The zero-drift limit had the lowest validation loss and set all four coefficients to zero for both tickers (Table S30). Final coefficients and feature scales were fitted using 2014–2024 only and saved before evaluating test forecasts. The two selection losses measure different things, so their magnitudes cannot be compared.

Table S30: Earlier-data selection of adaptive-volatility and direction-predicting model settings. Losses average ticker, year, and horizon groups equally across 2019–2024 validation blocks. Lower values are better within each selection task. The selected settings were EWMA decay 0.97 and the zero-drift limit.

Selection	Setting	Validation loss
EWMA decay	0.80	-2.921492
EWMA decay	0.90	-3.009741
EWMA decay	0.94	-3.044490
EWMA decay	0.97	-3.065558
EWMA decay	0.99	-3.064379
Ridge penalty	0.01	1.146523
Ridge penalty	0.1	1.143850
Ridge penalty	1	1.138475
Ridge penalty	10	1.136428
Ridge penalty	100	1.136142
Ridge penalty	1000	1.136112
Ridge penalty	Zero drift	1.136109

Historical close series for GS, LLY, and SPY shared the same recorded session grid, with 2,767 closes per ticker in 2014–2024 and 250 in 2025. The 2025 test updated lag features and variance using information through each origin while keeping fitted parameters fixed. The 2026 series began in April after a data gap. Its variance restarted from the 2014–2024 sample estimate and updated through the available April–July daily returns before evaluation. No daily return spanned the gap from December 2025 to April 2026. Within 2026, a daily return required closes on both adjacent trading sessions, and a missing observation left the variance unchanged. Feature windows used the last required number of valid daily returns, which could span more sessions when observations were missing. At evaluated 2026 origins, the most recent return used by the features was up to four calendar days old, whereas every 2025 origin had a return ending on the origin date. Complete five-session and one-session scores cover all four candidates and both periods (Tables S31 and S32). The direction-predicting and adaptive-volatility rows agree exactly because zero drift was selected. Their small median-error differences from the unchanged-price benchmark are Monte Carlo noise, since the population median of their forecast distribution equals the origin price. The saved outputs include seed-level scores, date-level comparisons, input hashes, and settings. The three seeds measure simulation variation alone.

Table S31: Complete five-session stock forecast scores for the four selected candidates. Each ticker has 245 origins in 2025 and 17 in August–September 2026. The MAE scores medians and the RMSE scores means. Monetary values are in dollars per share, and coverage and width describe central 90% intervals. Scores average dates within each of three 10,000-path runs and then average the runs. Direction-predicting equals Adaptive volatility because earlier-data selection chose zero drift.

Year	Stock	Model	Median MAE	Mean RMSE	CRPS	Coverage (%)	Width
2025	GS	JumpHMM	22.31	28.42	16.22	84.4	84.71

2026	LLY	Adaptive volatility	49.31	58.35	33.81	94.1	191.38
2026	LLY	Direction-predicting	49.31	58.35	33.81	94.1	191.38

Table S32: Complete one-session stock forecast scores for the four selected candidates. Each ticker has 249 origins in 2025 and 21 in August–September 2026. Units, point summaries, interval definitions, and aggregation follow Supplementary Table S31.

Year	Stock	Model	Median MAE	Mean RMSE	CRPS	Coverage (%)	Width
2025	GS	JumpHMM	9.10	12.26	6.66	87.8	34.66
2025	GS	Unchanged	9.13	12.28	9.13	–	–
2025	GS	Adaptive volatility	9.13	12.27	6.74	93.4	42.44
2025	GS	Direction-predicting	9.13	12.27	6.74	93.4	42.44
2025	LLY	JumpHMM	14.03	20.43	10.67	77.5	40.23
2025	LLY	Unchanged	14.07	20.44	14.07	–	–
2025	LLY	Adaptive volatility	14.06	20.43	10.63	93.3	67.61
2025	LLY	Direction-predicting	14.06	20.43	10.63	93.3	67.61
2026	GS	JumpHMM	10.67	14.34	8.00	90.5	52.39
2026	GS	Unchanged	10.59	14.23	10.59	–	–
2026	GS	Adaptive volatility	10.60	14.30	8.72	100.0	77.21
2026	GS	Direction-predicting	10.60	14.30	8.72	100.0	77.21
2026	LLY	JumpHMM	19.11	25.74	14.72	74.6	58.01
2026	LLY	Unchanged	19.01	25.79	19.01	–	–
2026	LLY	Adaptive volatility	18.98	25.78	14.47	76.2	83.93
2026	LLY	Direction-predicting	18.98	25.78	14.47	76.2	83.93

H Return Cutoffs and Sensitivity

Every JumpHMM price simulation used the truncated emissions in (1), with $b = 10$ as the primary cutoff and $b = 20$ as the wider sensitivity case. We set both cutoffs as stress assumptions before rerunning the affected experiments, without reference to the largest observed return. The truncation also applied to the state-inference likelihoods, and each experiment recomputed its pilot or ensemble normalization under each cutoff.

We converted the cutoffs to daily percentage returns using the pilot growth shift from the tests on later dates (Table S33). These are the widest possible daily returns over all fitted states, not forecast intervals. The removed mass is the probability cut from the standardized Student- t distribution, before state locations and scales are applied. Normalization constants differ slightly between experiments, so their daily limits differ slightly too.

Table S33: Daily return limits under the primary and wider cutoffs. The limits include the pilot growth shift from the tests on later dates and the 1/252 year step. Removed mass is the probability excluded from the original Student- t emission, in percent.

Stock	b	Lower return (%)	Upper return (%)	Removed mass (%)
GS	10	-26.47	38.99	0.0171
GS	20	-42.73	81.83	0.0006
LLY	10	-21.23	38.98	0.0171
LLY	20	-38.22	82.11	0.0006

The sensitivity comparison reran the GS and LLY illustrations, the IV ablation, both forecast cohorts, and the stock benchmarks with the same seeds and inputs at each cutoff. We compared short-call loss summaries for the illustrations and for the coupled-factor ablation after ten trading days (Table S34). We also compared five-session coupled option errors in the shorter-maturity cohort and JumpHMM stock scores (Table S35). The differences come only from the changed cutoff and the recomputed normalization constants.

Table S34: Short-call P&L sensitivity to the cutoff, in dollars per share. The illustration uses 1,000 paths and P&L at expiration. The coupled-factor ablation uses 3,000 paths and P&L from closing after ten trading days. Expected shortfall averages outcomes at or below the 5% quantile.

Experiment	Stock	b	Mean P&L	5% quantile	ES _{5%}
Ten-session ablation	GS	10	0.194	-35.194	-69.817
Ten-session ablation	GS	20	0.191	-35.203	-69.828
Ten-session ablation	LLY	10	6.260	-20.279	-45.182
Ten-session ablation	LLY	20	6.263	-20.273	-45.174
Terminal illustration	GS	10	-2.194	-86.183	-130.770
Terminal illustration	GS	20	-2.213	-86.243	-130.833
Terminal illustration	LLY	10	10.605	-51.956	-94.176
Terminal illustration	LLY	20	10.595	-52.006	-94.228

Table S35: Five-session forecast sensitivity to the cutoff. Option MAE scores the coupled-factor forecast mean in the shorter-maturity cohort. Stock CRPS scores the JumpHMM forecast distribution in each period. Values are in dollars per share and use the same date and seed weighting as the main comparisons.

Quantity	Stock	$b = 10$	$b = 20$	Change
Option MAE, 2026	GS	4.193743	4.200236	+0.006492
Option MAE, 2026	LLY	11.587739	11.587747	+0.000008
Stock CRPS, 2025	GS	16.221054	16.221403	+0.000349
Stock CRPS, 2025	LLY	29.604370	29.603983	-0.000386
Stock CRPS, 2026	GS	13.025558	13.025238	-0.000320
Stock CRPS, 2026	LLY	35.602434	35.601074	-0.001360
