Abstract

Valuing American options along simulated stock paths requires an implied-volatility (IV) input at every date, which a stock-return model alone does not provide. In this study, we developed a simulator that assigned an IV to American-style option contracts on simulated dates for any chosen stock model. We fitted parametric and neural IV surfaces, which predict IV from moneyness and time to expiration, to vendor option quotes for 31 tickers. Along stock paths from a jump hidden Markov model with capped daily returns, every option’s implied variance moved partway each day toward its surface prediction, following the Heston variance equation with random shocks that tended to raise IV when the stock fell, and a binomial tree converted that IV into option values and price sensitivities. Neural surfaces fitted by sector or ticker matched the quotes more closely than one parametric surface, although their errors varied by date and carried into dollar prices. Repricing identical stock paths under five ways of updating IV changed option values before expiration and the worst losses from closing short positions early, but not payoffs at expiration. In forecasts of later Goldman Sachs and Eli Lilly option prices, the stochastic IV update did little better than fixed IV, and rerunning the forecasts with the realized stock paths showed that stock-forecast errors caused most misses. The hidden Markov model and two simpler stock models tuned on earlier data all predicted stock prices about as accurately as assuming no change, and the one whose volatility adapted to recent returns improved predicted price ranges for Eli Lilly but not Goldman Sachs. The framework therefore supported reproducible comparisons of IV and stock assumptions but did not forecast better than simpler alternatives, and incomplete option histories, overlapping forecast dates, and simulated prices inconsistent across strikes limited broader use.

1 Introduction

Evaluating an option strategy requires a model of how contract values change as market conditions evolve. A position that appears profitable at expiration may incur losses before that date, when a trader may need to close or hedge it, so stress tests and trading-system studies require paths of option values and risk sensitivities as well as paths of the underlying stock price. American options add a further requirement because their values also reflect the opportunity to exercise before expiration. Historical option quotes provide observations of these quantities over realized market conditions, but a simulation must supply them for stock paths that have not occurred. Implied volatility (IV) provides a useful connection between market quotes and an option-pricing model because it is the volatility input recovered by inverting an observed price [Black and Scholes \[1973\]](#). To use this connection in a synthetic market, the simulator needs a rule for assigning IV across strikes and

*Corresponding author.

maturities and updating those values as the stock path unfolds. The stock model must also represent the return behavior relevant to the intended experiment, including features such as heavy tails and volatility clustering [Cont \[2001\]](#). The resulting problem is to simulate each option’s value on every date along each stock path in a way that shows how that value responds to the stock scenario.

Existing approaches address different parts of this problem through their choices of return dynamics, volatility representation, and pricing model. Parametric models such as stochastic alpha beta rho (SABR) and stochastic volatility inspired (SVI) provide compact descriptions of volatility smiles [Hagan et al. \[2002\]](#), [Gatheral \[2004\]](#). Neural methods allow more flexible representations and can accelerate pricing and calibration within specified volatility models [Horvath et al. \[2021\]](#), [Bayer and Stemper \[2018\]](#). Models of IV-surface dynamics describe changes in level, skew, and curvature through common factors [Cont and da Fonseca \[2002\]](#), with more recent methods incorporating static arbitrage constraints into surface simulation [Cont and Vuletić \[2023\]](#). Local- and stochastic-volatility models instead place stock and volatility dynamics within a joint pricing model [Dupire \[1994\]](#), [Derman and Kani \[1994\]](#), [Heston \[1993\]](#). These approaches can already generate option prices beyond the observed quotes. A different design question arises when the researcher wants to retain a physical stock-return model chosen for its empirical behavior and vary the volatility assumptions separately. Historical and generative return models can reproduce important features of equity data [Cont \[2001\]](#), [Wiese et al. \[2020\]](#), but their stock paths alone do not specify an option-implied volatility surface. For example, the Jump Hidden Markov Model (JumpHMM) generates returns through Markov transitions among return states and explicit visits to tail states [Alswaidan and Varner \[2026\]](#). Those returns determine what an option pays at expiration but leave its IV, and therefore its value, on earlier dates unspecified. A model that updates each option’s IV along the stock path can provide that input to a binomial tree that prices American options [Cox et al. \[1979\]](#), [Leisen and Reimer \[1996\]](#). This separation allows researchers to compare volatility assumptions on the same stock paths, provided that the accuracy of the resulting option prices and their consistency across strikes and expiration dates are checked explicitly.

In this study, we built a simulator that values American options along stock paths generated by JumpHMM. Before simulation, we fitted IV surfaces, which predict IV from an option’s moneyness (strike divided by stock price) and time to expiration, to observed option quotes. On each simulated date, every option’s implied variance then moved partway toward the surface prediction for its current moneyness and remaining time, following the mean-reverting variance equation of the Heston model [Heston \[1993\]](#) with random shocks that tended to raise IV when the stock fell, and a binomial tree converted that IV into the option’s value and price sensitivities. The stock model stayed unchanged, and the simulation used no option quotes from after the fitting period. Comparing one surface for all tickers, one per sector, and one per ticker on 234,549 observations from 31 tickers, we found that more flexible surfaces fitted to fewer tickers each had lower in-sample IV error, although on individual dates the surfaces still missed the overall IV level of some tickers and those misses carried into dollar prices. Accuracy on later dates was uneven, since errors varied widely across 53 tests that refitted the surfaces on all earlier dates and scored the next date, and they rose for surfaces fitted through July 2026 and tested on August and September quotes. Adding the time to scheduled earnings reports as a surface input reduced error when surfaces fitted on earlier April dates were tested on April 23 and 24. We then simulated Goldman Sachs (GS) and Eli Lilly (LLY) options and repriced the same stock paths under five ways of updating IV, from holding IV fixed at its starting value to the full update with random shocks, and found that the choice changed option values before expiration and the lower tail of profit and loss (P&L) from closing short positions early, while starting values and payoffs at expiration agreed exactly. Doubling the number of tree steps changed prices by less than 1% of these differences, so they were not numerical error, whereas a check of prices across strikes found GS prices that violated basic no-arbitrage conditions, mostly butterfly spreads priced below zero, and these violations remained with the finer tree. Forecasts of later GS and LLY option prices showed that the full IV update predicted option values almost no better than holding IV fixed, and repeating the forecasts with the stock paths that actually occurred, information unavailable when a forecast was made, cut option errors several-fold and showed that errors in the stock forecast caused most of the misses. We therefore compared JumpHMM with two simple stock models whose settings we chose on earlier data, one with volatility that adapted to recent returns and one that also predicted direction from recent returns, and found that every model predicted stock prices about as accurately as assuming no change, both in 2025 and in August and September 2026, whereas the adaptive-volatility model improved the predicted range of stock prices for LLY but not GS. Taken together, these results showed that the framework supported controlled

comparisons of IV assumptions on the same stock paths, that neither a more elaborate IV update nor the tested stock models forecast better than simpler alternatives, and that prices consistent across strikes and expiration dates remained a separate requirement before simulated prices could stand in for market prices.

2 Methods

2.1 Pipeline and stock-path generation

The framework connected stock-path generation to contract-specific IV dynamics and American-option valuation, with information passing through three stages in this order:

$$\text{JumpHMM stock path} \longrightarrow \text{contract IV factor} \longrightarrow \text{American lattice price and Greeks.} \quad (1)$$

Alpaca option data entered during the offline surface fit, after which each simulated step used that fitted surface without requiring a new option quote or feeding lattice prices back into the fit. Stock paths came from pretrained single-ticker JumpHMM marginals fitted to equity histories from 2014–2024 [Alswaidan and Varner \[2026\]](#). The model represents excess growth rates with latent states and location-scale Student- t emissions, and a jump mechanism increases visits to tail states to reproduce features such as heavy tails and volatility clustering [Cont \[2001\]](#). The pretrained artifact contained 424 ticker marginals with 50 states and 2,767 training days, and its growth rates used a 1/252 year step and zero risk-free offset. A Student- t copula can couple these marginals across assets [Demarta and McNeil \[2005\]](#), although the reported scenarios used one ticker at a time.

For price simulation, we replaced the unbounded Student- t emissions with their conditional distributions on a finite interval, so that the simulated excess growth rate in state k was defined by:

$$G_t = \mu_k + \sigma_k Z_t, \quad Z_t \sim t_{\nu_k} \mid |Z_t| \leq b, \quad b = 10. \quad (2)$$

The locations, scales, transition matrix, and jump parameters retained their training-fitted values, because the cutoff was a simulation assumption applied after fitting and we did not refit the model under a truncated likelihood. The cutoff was measured in units of the fitted Student- t scale rather than its standard deviation. We rejected and redrew out-of-bound emissions before applying the growth shift and converting log returns to prices, so every stock path was retained. This construction preserved the state and jump mechanism while giving finite stock-price moments at each fixed horizon, whereas exponentiating untruncated Student- t log returns gives an infinite stock-price mean and invalidates finite population interpretations of mean call values and short-call expected losses [Cassidy et al. \[2009\]](#). To examine sensitivity, we specified a wider cutoff $b = 20$ with the same contracts, seeds, and evaluation dates, recomputed normalization constants for each cutoff, and selected neither cutoff by forecast performance (Supplementary Tables [S29](#), [S30](#), and [S31](#)).

2.2 Offline IV-surface calibration

We downloaded option-chain snapshots daily from Alpaca Markets using a free account, which supplied Alpaca’s indicative feed, whose quotes are modified derivatives of the exchange feed rather than actual OPRA quotes [Alpaca Markets \[2026b\]](#). All option quote, midpoint, spread, and reported-IV comparisons in this study therefore refer to these captured vendor values and do not measure agreement with exchange-observed or executable prices. The frozen corpus contained 457 ticker files in fifteen snapshot directories and 234,549 observations after filtering, which required calls and puts to have a positive bid, positive calendar days to expiration (DTE), reported IV strictly between 0.01 and 2.0, and strike/spot between 0.8 and 1.2 inclusive, with spot taken as the stored underlying-session close. Both option types entered the same loss, and repeated contracts across snapshots remained separate observations. The calibration target was Alpaca’s reported IV field, which Alpaca documents as a Black–Scholes calculation with an iterative solver based on price sensitivity to volatility (Vega) [Alpaca Markets \[2026a\]](#). Snapshot labels and underlying-session dates defined the respective temporal splits (Supplementary Table [S1](#)). This corpus provided extensive cross-sectional coverage over a short observation window, which we used to compare a five-parameter log-polynomial with neural surfaces shared globally, within sectors, or fitted separately to individual tickers. Parametric models such as SABR and SVI motivate compact representations of IV smiles [Hagan et al. \[2002\]](#), [Gatheral \[2004\]](#), whereas neural representations allow more flexible shapes [Horvath et al. \[2021\]](#), [Bayer and Stemper \[2018\]](#). We exponentiated each shape function

to keep its output positive but imposed neither calendar monotonicity nor strike convexity during fitting, so the fitted surfaces required separate no-arbitrage checks. For ticker i , calendar days to expiration τ , and moneyness $m = K/S$, we used the following parametric shape:

$$\psi_\beta(\tau, m) = \exp[\beta_1 \ln \tau + \beta_2 \ln m + \beta_3 \ln \tau \ln m + \beta_4 (\ln m)^2 + \beta_5 (\ln \tau)^2]. \quad (3)$$

The corresponding IV prediction combined a ticker level with the surface shape:

$$\hat{\sigma}_i^2(\tau, m) = \theta_i \psi(\tau, m), \quad \theta_i > 0, \quad \psi(\tau, m) > 0, \quad (4)$$

and the fitted squared IV also defined the variance target on each observation date:

$$\theta_{\text{cal}}(i, \tau, m) = \theta_i \psi(\tau, m). \quad (5)$$

The neural network (NN) models replaced the log-polynomial with a positive network output, which defined the two-input neural surface:

$$\psi_{\text{NN}}(\tau, m; w) = \exp[\text{NN}(\text{std}(\ln \tau), \text{std}(\ln m); w)]. \quad (6)$$

Inputs were standardized using the training rows. Per-ticker fits required at least 2,000 observations, and tickers below that threshold retained sector fits. Networks with at least 5,000 per-ticker observations, or 2,000 pooled group observations, used a $2 \rightarrow 16 \rightarrow 16 \rightarrow 1$ architecture with tanh activations and 337 parameters, while smaller qualified groups used $2 \rightarrow 8 \rightarrow 8 \rightarrow 1$ with 105 parameters. For the earnings analysis, we appended two standardized inputs, the signed days to the ticker's nearest earnings date clipped to $[-30, 30]$ and the minimum absolute earnings distance among same-sector peers clipped to 30, which gave a $4 \rightarrow 16 \rightarrow 16 \rightarrow 1$ network with 369 parameters. Earnings dates came from the public Yahoo Finance calendar, and these event features entered only the temporal calibration comparison and remained inactive in the GS and LLY scenario drivers. We fitted each network representation by optimizing its weights and ticker log levels jointly to minimize the average squared difference between predicted and reported IV, a criterion that assigned equal weight to every retained observation:

$$\min_{w, \{\ln \theta_i\}} \frac{1}{n} \sum_{j=1}^n \left[\sqrt{\theta_{i(j)} \psi_{\text{NN}}(\tau_j, m_j; w)} - \sigma_{\text{market}, j} \right]^2. \quad (7)$$

The log levels were initialized from each ticker's mean squared market IV, and Adam training used a decreasing learning-rate schedule, at most 2,000 epochs, and a best-training-loss checkpoint with patience 200. Because a constant can be shifted between $\ln \theta_i$ and the output bias of the network, these two components are not separately identified, and only their product in (4) is interpretable without an additional normalization constraint.

2.3 Contract-specific dynamic IV factors

The standard Heston model couples an asset-price diffusion to a square-root instantaneous-variance process [Heston \[1993\]](#), whose variance follows the stochastic differential equation:

$$dv_t = \kappa(\theta - v_t) dt + \sigma_v \sqrt{v_t} dW_t^v. \quad (8)$$

Here κ is the mean-reversion rate, θ is long-run variance, and σ_v is volatility of variance, and the standard model correlates the variance Brownian motion with the Brownian motion driving the stock. We instead used the square-root process to evolve a separate implied-variance state for each contract along a stock path supplied by JumpHMM. Each state reverted toward a target from the fitted surface and supplied the volatility input for that contract's lattice price, which the lattice treated as constant within each pricing calculation even though it changed between simulated dates. The square-root process therefore served as a dynamic IV factor rather than as the underlying asset's instantaneous return variance in a standard Heston economy. Within this construction, each scenario contract $a = (i, K, T)$ received a variance state $v_{a,t}$ whose target changed with spot and remaining calendar DTE, and we obtained that target by evaluating the fitted surface at the current contract state:

$$\bar{v}_{a,t} = \theta_i \psi_{\text{NN}}(\tau_t, K/S_t). \quad (9)$$

The factor started exactly on the fitted entry surface,

$$v_{a,0} = \bar{v}_{a,0}, \quad (10)$$

and at each later date the lattice IV was the square root of that contract's factor:

$$\sigma_{a,t} = \sqrt{v_{a,t}}. \quad (11)$$

The put and call on a stock shared its path and variance shock but retained their own variance states and surface targets, and the stock and factor updates advanced only on exchange sessions. For the original fitted illustrations, we shifted every simulated growth-rate observation by a constant so that the ensemble mean matched a prespecified annual growth prior and then standardized the one-session log returns across all paths and dates, whereas the paired ablation used independent pilot estimates for these constants. The standardized return shock entering the IV update was defined by:

$$Z_{j,t}^S = \frac{\Delta \ln S_{j,t} - \overline{\Delta \ln S}}{s \Delta \ln S}. \quad (12)$$

An independent standard normal shock supplied the remaining variation, and combining the return and independent shocks gave the factor shock:

$$Z_{j,t}^v = \rho Z_{j,t}^S + \sqrt{1 - \rho^2} Z_{j,t}^\perp, \quad Z_{j,t}^\perp \sim \mathcal{N}(0, 1). \quad (13)$$

The coefficient ρ was fixed at -0.6 and acted as a return-shock coupling parameter rather than a calibrated correlation between two Brownian motions in a standard Heston model. We advanced each factor with a hard-floor Euler update and trading-year step $\Delta t = 1/252$:

$$v_{a,t+1} = \max \left\{ v_{a,t} + \kappa(\bar{v}_{a,t} - v_{a,t})\Delta t + \sigma_v \sqrt{\max(v_{a,t}, 0)} \sqrt{\Delta t} Z_{j,t}^v, v_{\min} \right\}. \quad (14)$$

We fixed $\kappa = 15$, $\sigma_v = 0.5$, and $v_{\min} = (0.005)^2$ as scenario assumptions, and the floor protected the numerical pricer when these parameters did not satisfy the Feller condition [Andersen \[2008\]](#). The repository also contains a proposed state-dependent level and aggregate tail-state mood multiplier, but both terms remained inactive in every reported experiment, so the fitted surface determined the target throughout the study and the fixed coefficient ρ determined return-shock coupling. Evaluating the additional mechanisms would require state-conditioned option histories.

2.4 American-option pricing, calendar clock, and terminal profit and loss

Recombining lattices price American options by comparing continuation with immediate exercise at every node during backward induction [Broadie and Detemple \[1996\]](#). The Cox–Ross–Rubinstein (CRR) construction sets its up and down factors from the supplied volatility [Cox et al. \[1979\]](#), and alternatives include the moment matches of Jarrow–Rudd and Tian [Jarrow and Rudd \[1982\]](#), [Tian \[1993\]](#) and the Peizer–Pratt inversion used by Leisen–Reimer to improve finite-step convergence [Leisen and Reimer \[1996\]](#). Both pricers used here accepted one IV value for a given contract and date. The GS and LLY contracts ran from April 28 to May 29, 2026, an interval of 31 calendar days and 22 exchange-session transitions after excluding weekends and the May 25 market holiday. The surface and lattice used calendar DTE, with $\tau_t/365$ years entering the pricer, while the stock and variance states advanced on the 22 trading transitions. Within this common clock, corpus-wide dollar-price checks used a 200-step CRR American tree and scenario marks and Greeks used a 201-step Leisen–Reimer (LR) American tree, both with a constant risk-free rate of 4.25% and continuous dividend yield $q = 0$. For low-volatility states or saturated Leisen–Reimer probabilities, an American CRR tree supplied the mark and retained the immediate-exercise comparison. At each trading transition, the simulation priced each contract at its current stock price, remaining maturity, and factor value before advancing the factor toward its moving target, and at expiration it replaced the lattice value with intrinsic value (Supplementary Algorithm S1).

We calculated terminal profit and loss for a short position that received the captured indicative mid-point p_0 as follows:

$$\Pi_T^{\text{put}} = p_0^{\text{put}} - \max(K - S_T, 0), \quad \Pi_T^{\text{call}} = p_0^{\text{call}} - \max(S_T - K, 0). \quad (15)$$

Terminal profit and loss in (15) therefore depended only on the JumpHMM terminal stock price, strike, and premium, so dynamic IV affected interim option marks and Greeks but not a held-to-expiration payoff. All option premiums, values, and P&L are dollars per underlying share, so monetary amounts for a standard 100-share contract are 100 times these values, and premium financing was omitted. We calculated price sensitivities, or Greeks, by central finite differences on

the same Leisen–Reimer pricer, with delta measuring price sensitivity to spot and gamma measuring the change in delta with spot. Spot bumps were $\pm 1.5\%$ of spot for delta and gamma, and volatility bumps were ± 0.005 , with Vega reported per one volatility percentage point. We assumed execution at the observed mid, no transaction costs, no margin constraint, no early assignment before the plotted horizon, and no discrete dividends.

2.5 Paired dynamic IV ablation

We tested which IV components changed interim valuation by holding the stock paths, contracts, entry premiums, and pricing assumptions fixed across five variants. Frozen IV retained each contract’s fitted entry value of v , the direct surface set $v_{a,t} = \bar{v}_{a,t}$ at every date, and deterministic mean reversion used (14) with $\sigma_v = 0$. An uncoupled stochastic factor used $\sigma_v = 0.5$ and $\rho = 0$, and the full factor used $\sigma_v = 0.5$ and $\rho = -0.6$, with $\kappa = 15$ in all three evolving variants. Every variant started at the same fitted entry IV and reused the same independent normal innovation wherever a stochastic factor was active. The evaluation applied this paired design to three seeds per ticker, 20260429, 20260430, and 20260431, with 1,000 paths per seed. A separate 10,000-path pilot with seed 20260905 supplied a constant growth shift to the 10% annual prior and the resulting one-session log-return mean and standard deviation, and we froze those constants before generating evaluation paths, so that, unlike the original fitted illustrations, the evaluation paths were not recentered or standardized using their own future realizations. The pilot and evaluation simulations each used 22 transitions, and every return was applied once after the initial stock price.

The primary endpoint was liquidation after ten trading transitions, on May 12 with 17 calendar days remaining, and secondary endpoints used five, fifteen, and twenty transitions. The short-position liquidation P&L and its paired difference from the direct-surface reference were given by the following expressions:

$$\Pi_{a,t}^{(b,j)} = p_{a,0} - P_{a,t}^{(b,j)}, \quad D_{a,t}^{(b,j)} = \Pi_{a,t}^{(b,j)} - \Pi_{a,t}^{(\text{surface},j)}. \quad (16)$$

Here b denotes the IV variant and j the shared stock path. We reported mean P&L, its standard deviation, the 5% quantile, and 5% expected shortfall, defined as mean P&L at or below that quantile. The paired mean difference had Monte Carlo standard error $s_D/\sqrt{n}$, with smaller values indicating more precise simulation estimates of that mean, and mean absolute mark differences measured the size of pathwise changes even when positive and negative differences canceled in the mean. We reported each seed separately and pooled 3,000 paths per ticker, and these uncertainty estimates were conditional on the fitted models and pilot constants.

We also checked exact agreement of entry marks and terminal payoffs across variants and examined the numerical accuracy and strike consistency of the intervening prices. Numerical checks compared 201- and 401-step marks on the first twenty paths of every evaluation seed at transitions ten and twenty. A separate strike audit used eleven fixed strikes from 0.8 to 1.2 times entry spot, the first fifty paths of the first seed, and transitions zero, ten, and twenty, with calls and puts at the scenario expiry sharing the same shocks. At both tree depths, we checked intrinsic and upper price bounds, strike monotonicity, vertical-spread bounds, and convexity, measuring convexity violations as the dollar excess above the neighboring linear interpolation and counting violations larger than \$0.01 per share, with entry counted once per variant and option type. These conditions are necessary for strike consistency, and the audit did not test calendar or dynamic no-arbitrage.

2.6 Chronological surface and forecast evaluation

We extended the temporal evaluation in two stages to distinguish surface transfer from forecasting complete contract paths. The first stage used the completed expanding-window sector-network experiment on 58 capture dates through July 17, 2026, in which each of 53 folds fitted the network to the first k dates and predicted the next captured date, with $k = 5, \dots, 57$. This experiment retained the original filters and capture-date labels, used two surface inputs, and calculated feature standardization from each training fold alone. Under an independent reconstruction of the saved row counts, its 986,492 accepted observations contained no crossed or missing asks and no missing or nonpositive displayed bid or ask sizes. Since prediction used the later observation’s stock price to calculate moneyness, the experiment measured conditional transfer of the surface across dates and evaluated neither stock forecasts nor the stochastic IV factor. The second stage fitted six sector networks once using 1,173,538 observations from 68 underlying sessions ending July 31, with architectures and a training schedule that matched the existing two-input sector model, seed 42, and a maximum of

2,000 epochs, and we saved training-loss checkpoints, ticker levels, and training-only standardization with the fitted models. The later sample contained 425,061 filtered IV observations across 23 sessions from August 4 through September 4, which supplied the final evaluation and did not select architectures, fitting windows, parameters, or seeds.

The second stage used an explicit capture audit before fitting or selecting contracts. The collector recorded retrieval times in UTC and stored the underlying-session close with each option row, and we accepted retrievals after 20:00 UTC on that session and before 13:30 UTC on the next exchange session, a rule that admitted overnight retrievals of a previous close while excluding twenty intraday repeat captures. We retained the latest eligible file per ticker and underlying session and one row per exact option symbol. Two-sided quotes required finite positive bids, noncrossed asks, and positive displayed sizes, and surface fitting additionally required the original IV and moneyness ranges and positive DTE recomputed from expiration and the underlying session. Only files retrieved by the end of July 31 could enter training. Because retrieval times were not exchange quote timestamps, this audit did not establish quote freshness or exact stock–option synchronization, a limitation that applied to the interpretation of both IV and dollar-price errors.

The forward test used GS and LLY at successive observed origins in August and early September, with planned horizons of one and five exchange sessions and one put and one call with 25–45 calendar DTE at each origin. For each option type, we selected the expiration nearest 31 DTE and then the strike nearest $K/S = 0.95$ for puts or 1.05 for calls, breaking ties by earlier expiration and symbol and using only the origin observations. We matched each selected symbol at its exact endpoint session and recorded missing endpoints without substituting another contract or capture date. Because the collection’s rolling maturity buckets left none of these roughly monthly contracts observed five sessions later, we retained their one-session evaluation and added a separate shorter-maturity cohort with 10–21 DTE, choosing the expiration nearest 14 DTE with the same strike and tie rules. This availability-driven amendment preceded inspection of aggregate forecast errors and was recorded in the experiment protocol, and the shorter cohort supplied the five-session case study without replacing the original contracts or validating their longer trajectories. All five IV variants began at the contract’s observed origin IV, and to compare their evolution without confounding the result with the fitted surface’s initial level error, we rescaled the frozen variance target once at the origin:

$$\bar{v}_{a,t}^* = \sigma_{a,0,\text{obs}}^2 \frac{\bar{v}_a(S_t, \tau_t)}{\bar{v}_a(S_0, \tau_0)}. \quad (17)$$

This anchoring defined a separate forecast experiment, whereas the original sensitivity ablation retained its fitted initialization. Frozen IV held the common origin value, direct evaluation followed $\bar{v}_{a,t}^*$, and the three evolving factors used that anchored target with the previously specified parameters. Each origin used 1,000 JumpHMM paths with normal innovations shared across IV variants, and the initial return state was drawn from the saved model’s stationary distribution, so recent returns did not update that state in the original forecast. An independent 10,000-path pilot per ticker supplied the growth shift to the existing 10% annual prior and the one-session return normalization, and evaluation paths were not recentered. A zero-log-drift Gaussian random walk with the pilot return standard deviation provided a stock benchmark. Origin stock prices and IV updated as observations became available while fitted parameters remained fixed, so the test was a retrospective evaluation at successive forecast origins rather than a single forecast issued on July 31.

We scored forecast mean option values against the later bid–ask midpoints, using mean absolute error as the prespecified primary point metric, and added median-based absolute errors to distinguish the choice of point summary from the IV comparison. Signed error, root mean squared error, and the fraction of predicted means inside the quoted spread supplied complementary price diagnostics. Distributional evaluation used the empirical continuous ranked probability score (CRPS) [Gneiting and Raftery \[2007\]](#), which rewards concentration near the observed value while penalizing misplaced probability mass, and for N simulated values P_j and observed midpoint y we calculated the score as:

$$\text{CRPS} = \frac{1}{N} \sum_{j=1}^N |P_j - y| - \frac{1}{2N^2} \sum_{j=1}^N \sum_{k=1}^N |P_j - P_k|, \quad (18)$$

where smaller values indicate better distributional forecasts. We also reported central 90% interval coverage and width, averaged scores across matched contracts within each ticker and origin before averaging dates, and reported stock forecast scores separately. A diagnostic repeated IV evolu-

tion using the observed stock path only when every intervening session was available, and because it was explicitly conditional on realized stock information, it did not constitute a joint forecast. Repricing with the endpoint’s reported IV in the same lattice supplied a further diagnostic of pricing discrepancies, and all monetary scores were dollars per share. Overlapping horizons and common market movements made forecast dates and contracts dependent, so simulated path counts were not treated as independent market observations. The illustrative forecast was the earliest GS origin in the shorter-maturity cohort with both selected contracts observed at the five-session endpoint, chosen regardless of its forecast errors.

2.7 Stock forecast benchmarks

The option forecast errors motivated a separate evaluation of the stock generator. We first checked return scaling and price reconstruction and repeated the 2026 stock forecasts after conditioning the initial state on the available return history, a diagnostic that retained the fitted parameters and tracked the remaining duration of a jump episode during state inference. We then compared four stock forecast methods: the saved 2014–2024 JumpHMM, an unchanged-price benchmark, a Gaussian model with adaptive volatility, and the same volatility model with a simple directional regression. The original JumpHMM retained its stationary initialization and independent-pilot growth shift, while the adaptive model updated daily variance with an exponentially weighted moving average (EWMA) of squared log returns. The regression estimated a daily drift from the stock’s most recent one, five, and twenty valid daily returns and SPY’s most recent five valid daily returns, normalized the cumulative-return features by origin volatility and the square root of their window length, and shrank the coefficients toward zero with a ridge penalty and no intercept. With $u_t = \log(S_t/S_{t-1})$ denoting an observed daily return and a_t its estimated daily variance at the forecast origin, the adaptive and directional models used the equations:

$$a_t = \lambda a_{t-1} + (1 - \lambda) u_t^2, \quad \log \frac{S_{t+h}}{S_t} = h\mu_t + \sqrt{a_t} \sum_{j=1}^h Z_j, \quad Z_j \sim \mathcal{N}(0, 1). \quad (19)$$

The adaptive model set $\mu_t = 0$, while the directional model used the regression estimate, and because drift and variance remained fixed within each forecast horizon, neither model received future stock or market returns. The unchanged-price benchmark supplied only a point forecast and was not assigned an uncertainty interval for comparison with the stochastic models. These stock tests did not replace the paths used in the original option evaluation or the paired IV ablation.

We selected the new models’ settings using expanding annual validation blocks from 2019 through 2024, with earlier observations used for each regression fit and feature scale, and chose one EWMA decay and one ridge penalty across both tickers by weighting each ticker, validation year, and horizon equally. Candidate decays were 0.80, 0.90, 0.94, 0.97, and 0.99, and ridge penalties ranged from 0.01 to 1000 and included the zero-drift limit. Decay selection minimized Gaussian log loss for cumulative log returns, while penalty selection minimized squared cumulative-return error divided by forecast variance. After selection, we fitted the regression using 2014–2024 observations and froze its coefficients and scaling. The additional 2025 stock dataset supplied 249 one-session and 245 five-session origins per ticker, and the August–September 2026 test retained the original 21 one-session and 17 five-session stock outcomes per ticker, with identical starting prices and endpoints for all methods. Origin features and variance updated only with observations then available, and missing closes were neither filled nor converted into multi-session returns treated as one-day observations. Each stochastic model used 10,000 paths per origin and three fixed simulation seeds, with shared Gaussian innovations between the adaptive and directional candidates. We reported median-based MAE, mean-based RMSE, CRPS, and central 90% interval coverage and width, since medians minimize expected absolute loss and means minimize expected squared loss [Hyndman and Athanapoulos \[2021\]](#), and we averaged scores across dates within each simulation replicate and then across replicates. The model classes were proposed after inspecting the original 2026 misses, but neither the 2025 nor 2026 outcomes selected their settings, so we reported both periods separately and treated the 2026 follow-up as exploratory. Every JumpHMM price simulation used the truncated emissions in (2), which also entered the emission likelihoods for the state-initialization diagnostic, whereas the Gaussian benchmarks and their historically selected settings were unchanged.

3 Results

We fitted global parametric, global neural, and sector-specific neural surfaces to the calibration corpus and observed lower in-sample IV error as surface flexibility increased and parameter sharing narrowed (Table 1). The filtered corpus contained 234,549 observations from 31 tickers across fifteen snapshots and six market groups (Supplementary Tables S2 and S1), and every model used the same loss and retained ticker-specific levels. Root mean squared error (RMSE) measured agreement with reported IV in volatility percentage points, with lower values indicating a closer fit, and we compared models through their predicted IV because the ticker level and neural output bias were not separately identified in (4). Replacing the global parametric shape with a global neural surface reduced pooled in-sample error from 12.48 to 11.47 points, and sector-specific networks reduced it further to 10.24 points. The sector gains extended across all six groups and were largest in exchange-traded funds (ETFs) and financials (Supplementary Table S3), whereas technology and healthcare retained the largest errors and contained the weakest individual ticker fits (Supplementary Table S7). These remaining differences motivated separate surfaces for tickers with sufficient observations. Assigning per-ticker networks where the sample threshold was met, while retaining sector fits for the remaining tickers, reduced pooled error to 9.73 points, 22% below the parametric reference, and most qualified tickers improved under this change (Supplementary Table S4). Pooled calibration error alone could not show whether the fits were accurate on individual dates, in dollar prices, or on later observations, and we examined each of these in turn.

Table 1: In-sample IV RMSE on 234,549 observations, reported in volatility percentage points. Each model fitted one ticker level jointly with its shape parameters. The final row used per-ticker neural surfaces for the 29 qualified tickers and sector surfaces for PFE and BMJ.

Model	RMSE	Reduction from parametric
Parametric shape, global	12.48	reference
Neural shape, global	11.47	8.1%
Neural shape, six sectors	10.24	17.9%
Neural shape, per-ticker with fallback	9.73	22.0%

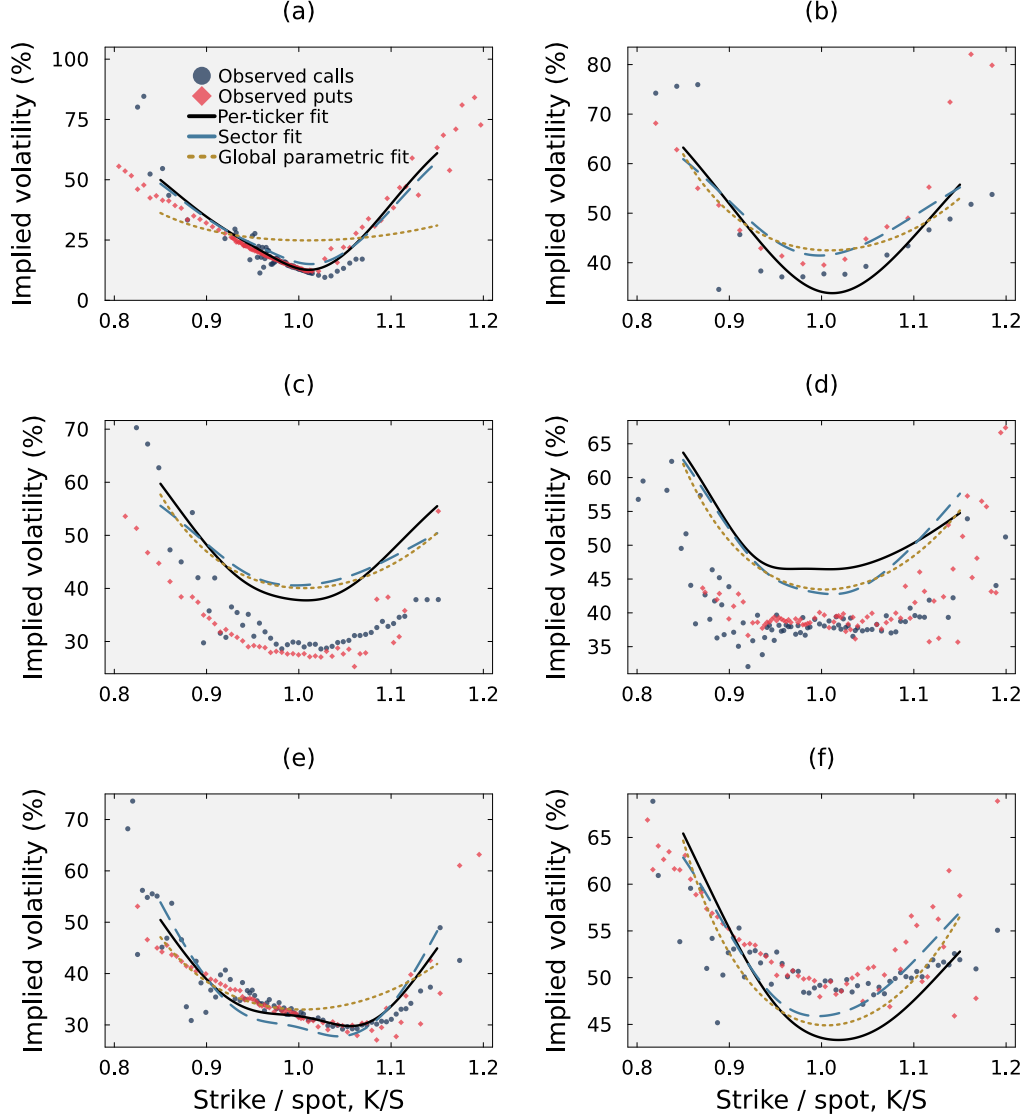

Figure 1: In-sample comparison of the implied volatility (IV) observed on May 11, 2026 with surfaces fitted across all fifteen calibration snapshots. Panels show (a) SPY, (b) NVDA, (c) MSFT, (d) LLY, (e) GS, and (f) AVGO, with 7, 7, 9, 11, 11, and 9 calendar days to expiry, respectively. Circles and diamonds distinguish reported call and put IV; solid, dashed, and dotted curves show per-ticker neural, sector neural, and global parametric fits. The legend applies to all panels. The MSFT and LLY fits overpredict IV near the money (Supplementary Table S5).

We then compared the fitted surfaces with observations from the May 11 capture and found date-specific level errors that carried through to option prices (Figs. 1 and 2). All three displayed surfaces had been fitted across the fifteen snapshots that included this date, so the comparison was in-sample. Near the money, the per-ticker fits exceeded observed IV by an average of 9.45 percentage points for MSFT and 7.90 points for LLY, whereas the corresponding biases were small for SPY and GS and AVGO was underpredicted by 5.37 points (Fig. 1; Supplementary Table S5). These discrepancies appeared at the observed contracts themselves, and a surface with moneyness and maturity as its only inputs could not adjust its level independently for a single date. To measure the pricing consequences, we passed the fitted IV predictions to the American lattice and judged each dollar error against the local bid-ask half-spread, since the same IV error can have different pricing consequences across contracts and an improvement in pooled IV fit need not place a model price within

the quoted spread. Only about one third of fitted SPY, NVDA, and LLY prices fell within the half-spread around the mid, compared with 88% for GS (Fig. 2; Supplementary Table S6), and LLY had the largest median absolute error at \$4.01 per share. Repeating the calculation with each contract’s reported IV in the same lattice cut the LLY median error six-fold, to \$0.67 per share, which pointed to the surface’s date-specific IV level as a major contributor. The remaining errors also showed that the reported IV did not reproduce every captured mid under the American pricer. Greater flexibility and narrower sharing therefore improved the pooled fit without removing date-level errors, which made dollar-price accuracy a separate requirement alongside IV fit.

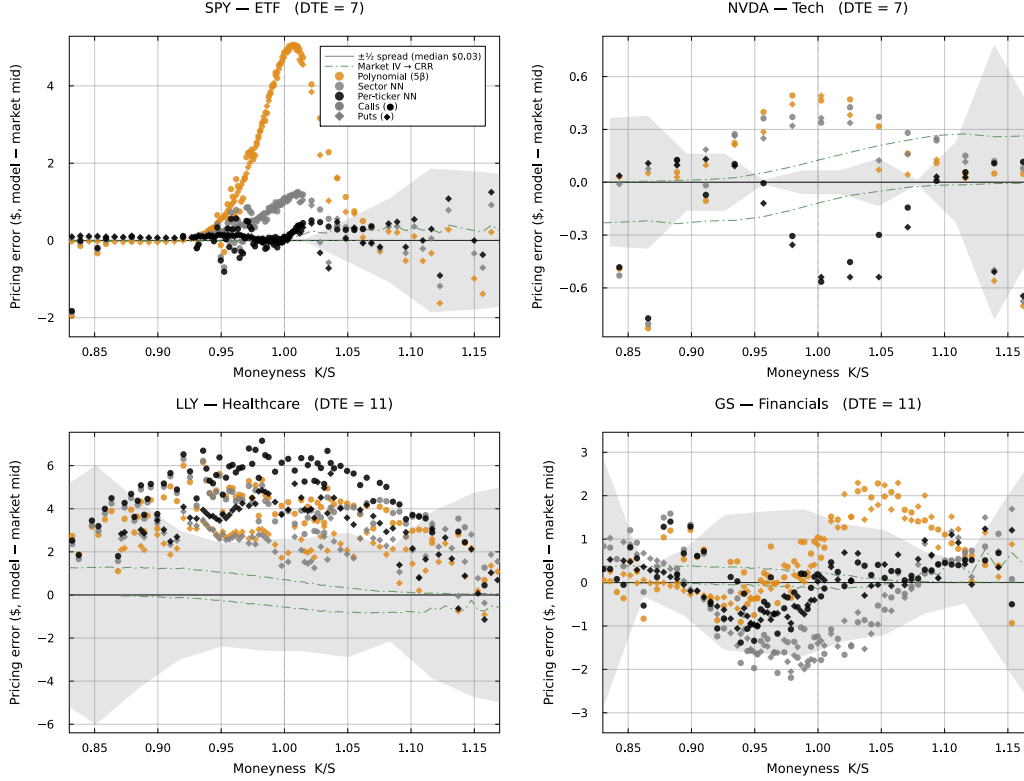

Figure 2: In-sample comparison of CRR American-option prices with Alpaca indicative mids across moneyness for SPY, NVDA, LLY, and GS on May 11, 2026. Errors are lattice price minus indicative mid. Curves show the parametric, sector, per-ticker, and reported-IV reference inputs. The gray ribbon is the median local bid-ask half-spread by moneyness bin. A point inside the ribbon has an absolute pricing error below that local half-spread.

We next withheld dates from training and observed higher errors on the withheld dates, which earnings-calendar inputs reduced on a fixed holdout (Table 2). Removing May 11 and retraining the sector models on the other fourteen dates gave pooled error of 10.21 volatility percentage points on the training observations and 10.89 points on the holdout, with the largest increases in energy and retail, so the modest pooled gap concealed differences among sectors (Supplementary Table S8). A separate temporal split then tested whether calendar inputs supplied information beyond moneyness and maturity. Configuration A used those two inputs alone, while Configuration C added distances to ticker and peer earnings dates on exactly the same training and test rows. The added inputs reduced error on the two-day holdout from 13.03 to 11.98 volatility percentage points, and several technology tickers with nearby peer reports improved, although the gains did not extend to every ticker (Supplementary Table S9). Configuration B removed observations near earnings before fitting the two-input model and produced similar training and test errors, but because it discarded most observations and changed the composition of both samples, it could not attribute the original error gap to earnings alone. Every test ticker appeared in training, and neither temporal experiment covered repeated dates and training seeds, so these results supported limited transfer within the available window and a benefit from earnings inputs on one fixed holdout.

Table 2: Temporal-holdout comparison. Training used six snapshots labeled April 14 through April 22, 2026, and testing used April 23–24; every test ticker appeared in training. Errors and gaps are in volatility percentage points. Configuration B used different row sets from A and C.

Configuration	N_{tr}	N_{te}	Train RMSE	Test RMSE	Gap
A: pooled, two inputs	103,897	26,833	8.05	13.03	+4.99
B: non-earnings, two inputs	29,383	4,516	8.02	7.96	−0.06
C: earnings-aware, four inputs	103,897	26,833	7.61	11.98	+4.36

Having evaluated the fitted surfaces, we used them to simulate complete GS contract paths and observed option values that followed the stock path and IV factors that differed between the put and call (Figs. 3 and 4). We selected one put and one call for each of GS and LLY from the April 28 capture with expiration on May 29 (Supplementary Tables S11 and S12). The initial illustrations used 1,000 stock paths per ticker and a separate IV factor for each contract under the fixed settings in Supplementary Table S10, with each factor following a moving target from the fitted surface before its IV entered the lattice at the current stock price and remaining maturity. The GS paths showed the expected inverse relation between terminal stock and put payoff and the direct relation between terminal stock and call payoff (Fig. 3). Before expiration, the put and call factors followed different targets as moneyness and calendar days to expiration changed, and their shared negative return coupling tended to increase factor shocks after lower standardized returns (Fig. 4). The LLY paths applied the same calculation under a different return marginal and a higher fitted IV level (Supplementary Figs. S2 and S3), and the pathwise Greeks for both tickers showed delta approaching the exercise states, gamma concentrating near the strike, and Vega declining toward expiration (Supplementary Figs. S1 and S4). These illustrations standardized return shocks across the completed ensemble (Supplementary Algorithm S1), whereas the paired ablation used independent pilot constants to measure the contribution of IV dynamics on shared evaluation paths. Both experiments used surfaces fitted with observations from the scenario period, so they illustrated the behavior of the assembled model rather than forecasting later observations, which the chronological tests evaluated with separate fits and origins.

We next held each short position to expiration and observed frequent premium retention alongside lower-tail losses (Supplementary Tables S11 and S12). For a position held to expiration, terminal P&L was the entry premium minus the payoff determined by the final stock price and strike. In GS, the short put retained its full premium on 74.0% of paths and the short call on 67.7%, yet the worst 5% of outcomes lost at least \$58.96 per share for the put and \$86.18 for the call, 3.6 and 5.4 times their entry premiums. Those less frequent losses left mean P&L positive for the put but negative for the call. The market-delta heuristic $1 - |\Delta|$ gave premium-retention estimates of 70.5% and 67.2% for the same contracts. The LLY put and call retained their premiums on 80.7% and 79.3% of paths, respectively, both with positive mean P&L under the scenario assumptions, and these frequencies exceeded the heuristic by 11.0 and 10.2 percentage points. The larger gaps than in GS showed that agreement between the heuristic and simulated strike crossing depended on the ticker and scenario, since quote delta came from a risk-neutral pricing calculation whereas the simulated frequencies came from physical stock paths. Because terminal P&L depended only on the stock path, strike, and premium, these results characterized the chosen return distributions and contract inputs and did not test the fitted surface or the dynamic factor, which required changing the IV module while holding the stock paths and terminal payoffs fixed.

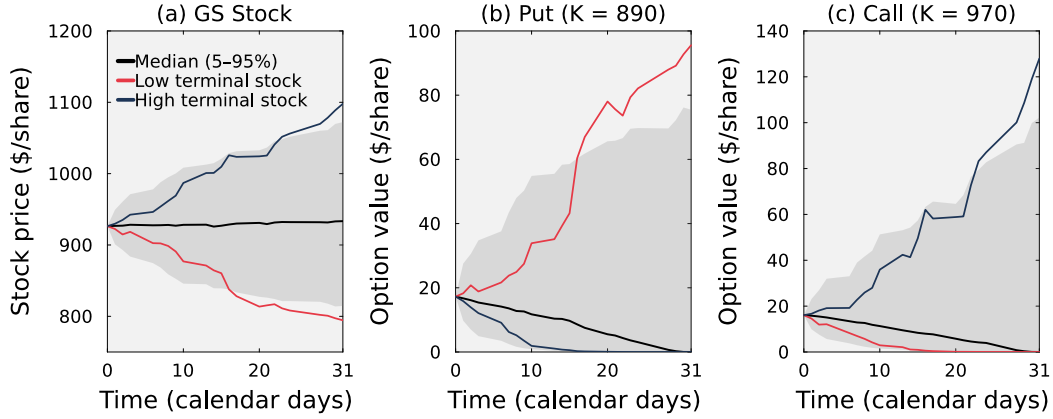

Figure 3: Simulated evolution of GS stock prices (a), put values (b), and call values (c) along 1,000 paths between April 28 and May 29, 2026. The fitted surfaces included observations from this scenario period, so these paths illustrate the model rather than an out-of-sample forecast. Time is measured in calendar days from April 28. Black curves show the median at each date, and shaded bands contain the middle 90% of values. Red and blue curves show group medians for paths ranked in the 1st–5th and 95th–99th percentiles of terminal stock price. These summaries are not individual trajectories. Option values are dollars per share and represent the cost of repurchasing the contract for a short seller. Entry premiums were \$16.51 per share for the put and \$16.09 for the call.

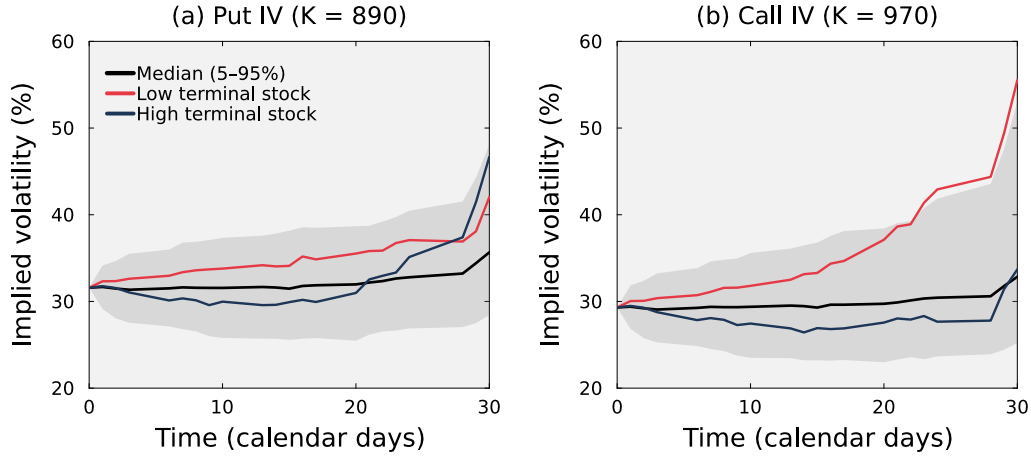

Figure 4: Simulated evolution of annualized IV at the GS put strike (a) and call strike (b). These factors belong to the illustrative scenario in Fig. 3. Both panels express IV as percentages on the same vertical scale. Curves show pointwise medians across all 1,000 paths and within the terminal-stock groups defined in Fig. 3; shading shows the 5th–95th percentile band. Time is measured in calendar days from April 28, 2026, and stops before expiration. IV does not enter the expiration payoff.

We therefore compared five IV variants on identical stock paths for the four scenario contracts and found that IV dynamics changed interim option values and the lower tail of liquidation P&L (Fig. 5; Supplementary Table S13). The comparison held contracts, entry premiums, and pricing assumptions fixed so that differences in interim marks could be attributed to the IV module. After ten trading transitions, the full factor changed marks by a mean absolute \$1.77–\$2.41 per share relative to direct surface evaluation. For the GS put, the \$1.77 mean absolute change was about 35 times the \$0.05 decrease in mean P&L, which had a paired Monte Carlo standard error of \$0.04, so positive and negative differences largely canceled when averaged across paths. Frozen IV and deterministic mean reversion also produced different marks from the direct surface, showing that movement of the target and persistence around it affected valuation even without stochastic shocks. Comparing the coupled and uncoupled factors on the same paths showed how return coupling changed valuation across stock outcomes, with short-put P&L declining most on falling-stock paths and short-call P&L improving most on rising-stock paths for both tickers (Fig. 5). Coupling also changed the lower tails of short-position P&L, which we measured with 5% expected shortfall, defined as mean P&L at or below its 5% quantile, so that more negative values indicate larger simulated losses. Negative coupling moved the GS put’s expected shortfall from $-\$62.98$ under uncoupled factors to $-\$64.60$ under the full factor, whereas the call’s improved from $-\$71.53$ to $-\$69.82$, and the LLY contracts showed the same direction of change (Supplementary Table S13). The full-factor mean absolute mark differences were similar across the three evaluation seeds (Supplementary Table S14), and all variants produced identical entry marks and terminal payoffs. The experiment thus located the contribution of IV dynamics in interim valuation and liquidation risk while preserving the stock paths and terminal outcomes.

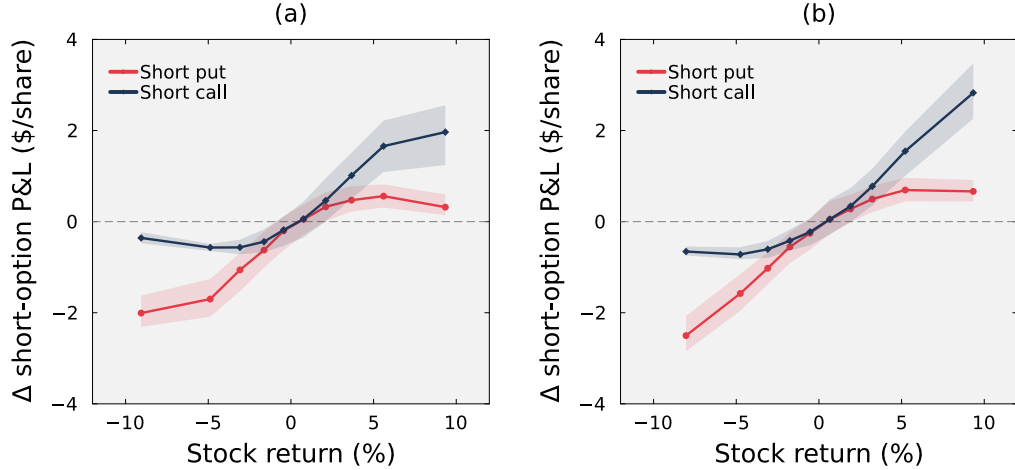

Figure 5: Effect of return coupling on interim short-option P&L as a function of stock return after ten trading transitions for (a) GS and (b) LLY. Each difference is coupled-factor P&L ($\rho = -0.6$) minus uncoupled-factor P&L ($\rho = 0$) on the same stock path, with the same independent normal innovations. Negative values indicate worse short-position P&L under coupling. The 3,000 paths per ticker are sorted by stock return and divided into ten groups of 300. Symbols show median paired P&L differences at median stock returns; connecting lines guide the eye, and shaded bands span the within-group 25th–75th percentiles. These bands describe variation across paths, not confidence intervals. Red circles denote puts and navy diamonds denote calls. All marks are evaluated on May 12, 2026, with 17 calendar days to expiry.

We then refined the lattice and audited strike consistency, and found that the ablation differences exceeded numerical error but that the GS prices violated some necessary strike conditions (Supplementary Table S15). Increasing lattice depth from 201 to 401 changed sampled marks by at most \$0.0017 per share, more than two orders of magnitude below the mean absolute differences among IV variants. No factor reached the variance floor in the four scenario contracts, although current strike/spot left the training interval on 0.7–2.9% of pre-expiry path dates across ticker, contract, and seed combinations, so some marks used extrapolated surface values. The strike audit tested necessary conditions across separately priced contracts. At 401 lattice steps, the direct GS

surface exceeded the \$0.01 convexity tolerance in 178 of 1,818 tested strike triples, with a largest excess of \$0.113 per share, and the GS full factor had three monotonicity violations among 2,020 adjacent-strike comparisons, with a maximum of \$0.013. These violations persisted at the higher lattice depth, whereas no LLY variant violated the tested conditions at the stated tolerance. Single-contract lattice accuracy therefore did not ensure consistency across strikes, and the residual GS violations limited the use of the generated prices as market-consistent training data even though the same outputs supported controlled comparisons of IV assumptions.

We extended the surface evaluation beyond the original April–May window and observed uneven transfer to later dates (Supplementary Tables S16 and S17). The completed expanding-window experiment evaluated two-input sector networks on 53 successive held-out capture dates through July 17, with a median test RMSE of 9.92 IV percentage points but individual folds ranging from 7.68 to 19.25 points (Supplementary Table S16). Each fold used the later observation’s stock price to determine moneyness, so the result concerned conditional IV prediction rather than a forecast of the stock–option system. We then fitted a single set of sector surfaces through July 31 and evaluated the 23 later sessions from August 4 through September 4, where pooled RMSE increased from 10.79 points in training to 14.75 points in the held-out sample (Supplementary Table S17). These values were not a paired comparison with the earlier folds because the fitting window, capture audit, and evaluation dates differed. The GS surface had held-out RMSE of 6.30 points and mean overprediction of 0.88 points, whereas LLY had RMSE of 9.96 points and mean overprediction of 4.61 points, more than five times the GS bias. The larger corpus therefore did not remove the problem of a frozen surface level lagging a later market state, which motivated a separate forecast comparison in which all IV variants started from the observed origin IV and differed in their subsequent evolution.

We next compared forward option forecasts with later observations of the same selected contracts and found nearly identical errors under the coupled factor and frozen IV (Table 3). The maturity-bucket collection scheme imposed an immediate limit, because none of the 36 eligible roughly monthly contracts per ticker had an observed exact-symbol endpoint after five sessions (Supplementary Table S18). Their one-session comparison retained 34 quotes across 17 origins per ticker, with coupled-factor MAE of \$3.79 per share for GS and \$6.08 for LLY, compared with \$3.80 and \$6.11 under frozen IV (Supplementary Table S19). The separately identified shorter-maturity cohort supplied five-session outcomes for 34 GS and 30 LLY quotes across 17 origins per ticker. Coupling again produced only small reductions in the absolute error of the forecast mean, with MAE of \$4.19 versus \$4.21 under frozen IV for GS and \$11.59 versus \$11.62 for LLY, and it improved date-level MAE on six of seventeen GS origins and nine of seventeen LLY origins, so the small average reductions were not consistent across dates. Scoring forecast medians separately lowered GS coupled-factor MAE to \$2.48 and gave LLY MAE of \$11.79, with little separation from frozen IV (Supplementary Table S23). The coupled model’s CRPS was 2.01 for GS and 8.93 for LLY, compared with 2.02 and 8.99 under frozen IV. Central 90% intervals had date-weighted coverage of 100% for GS and 67.6% for LLY, with average widths of \$25.65 and \$28.91 per share, so the GS intervals covered every endpoint whereas LLY coverage fell 22 percentage points below the nominal level. In the earliest eligible GS origin, the coupled and frozen-IV mean forecasts nearly coincided while the observed call value declined below both (Fig. 6). The fixed stochastic factor therefore showed no material forecasting advantage over frozen IV in this case study.

Table 3: Five-session option forecasts for the shorter-maturity cohort, selected with 10–21 calendar DTE at each origin. Scores average matched contracts within each ticker and origin before averaging dates. MAE scores the forecast mean; MAE, CRPS, and central 90% interval width are dollars per share. Coverage is date-weighted. Every IV variant uses the same stock paths, origin IV, and matched quotes.

Ticker	IV variant	Dates	Quotes	MAE	CRPS	Coverage (%)	Width
GS	Frozen IV	17	34	4.21	2.02	100.0	25.64
GS	Direct surface	17	34	4.86	2.16	67.6	24.01
GS	Mean reversion	17	34	4.26	2.02	100.0	25.62
GS	Uncoupled factor	17	34	4.24	2.03	100.0	25.69
GS	Coupled factor	17	34	4.19	2.01	100.0	25.65
LLY	Frozen IV	17	30	11.62	8.99	73.5	28.98
LLY	Direct surface	17	30	11.62	9.05	55.9	26.68
LLY	Mean reversion	17	30	11.62	8.99	73.5	28.83
LLY	Uncoupled factor	17	30	11.61	8.97	73.5	28.83
LLY	Coupled factor	17	30	11.59	8.93	67.6	28.91

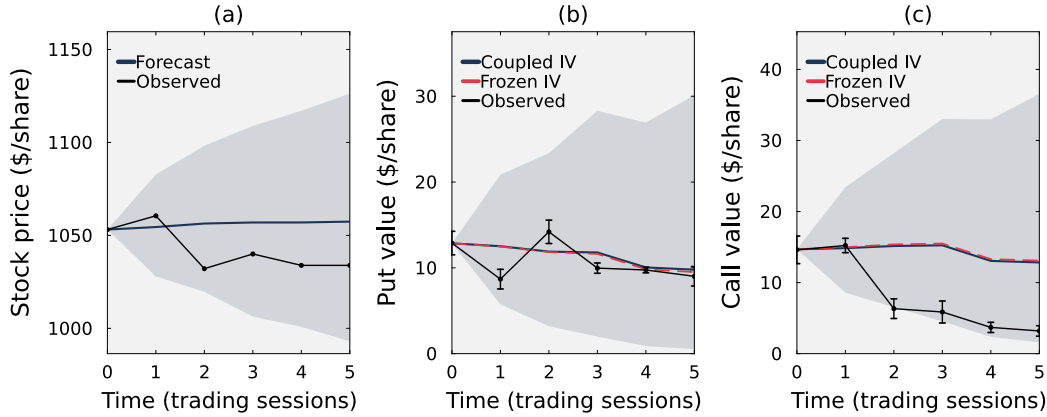

Figure 6: Five-session forecasts of GS stock prices (a), put values (b), and call values (c), compared with observations from August 4 to August 11, 2026. The put strike is \$1,000, the call strike is \$1,105, and both contracts expire on August 21. Forecasts use the July-cutoff surface and information available at the August 4 origin. Navy curves show forecast means from 1,000 stock paths, with the coupled IV factor used for option values; shading spans the central 90% of simulated values. Red dashed curves show frozen-IV mean option forecasts on the same stock paths. Black points show observed stock closes and option midpoints, with vertical bars spanning Alpaca’s indicative bid and ask. These option observations are vendor values rather than exchange quotes. Time is measured in exchange sessions from the origin. This is the earliest GS origin with both selected shorter-maturity contracts observed at the five-session endpoint.

We then replaced the simulated stock paths with the observed paths and found that stock-forecast error accounted for most of the option-price miss (Supplementary Table S20). Complete intervening stock observations were available for thirteen five-session origins per ticker, with 26 matched GS quotes and 24 LLY quotes. On these cases, the substitution cut coupled-factor MAE 3.8-fold for GS, from \$4.62 to \$1.23 per share, and 5.4-fold for LLY, from \$10.61 to \$1.95. The observed path was unknown at the origin, so this diagnostic located the error rather than correcting it. Within the diagnostic, frozen IV had lower point errors of \$1.07 and \$1.74, while uncoupled stochastic factors had lower CRPS than the coupled factor for both tickers. The retained JumpHMM settings also gave no point-forecast advantage for the stock itself, with five-session stock MAE of \$16.85 for GS and \$49.83 for LLY versus \$16.17 and \$48.64 for the simple random walk (Supplementary Table S21). Repricing the shorter-maturity endpoint observations with their reported IV reduced five-session option MAE to \$0.14 for GS and \$0.34 for LLY, and those prices lay within every observed bid–ask

interval (Supplementary Table S22). Sampled lattice refinement changed marks by at most \$0.0026 per share across the two cohorts, below the forecast errors. Stock-forecast error therefore dominated the option-price misses, smaller errors remained in the IV and pricing inputs, and no dynamic IV variant was reliably superior.

We next asked whether a different stock forecast could reduce these misses without future information, and found that central forecasts from every tested method remained close to an unchanged-price benchmark (Table 4). Return-scaling checks and reconstruction of the saved paths found no error in the conversion from annualized log growth to daily prices. Conditioning the initial state on recent returns did not materially improve five-session central forecasts, changing median-based stock MAE from \$16.28 to \$16.36 for GS and from \$49.58 to \$49.40 for LLY (Supplementary Table S25), because the effect of the initial state on the forecast distribution largely disappeared within a few sessions under the fitted transitions. We then compared the retained JumpHMM with unchanged-price, adaptive-volatility, and simple directional benchmarks, using earlier data to select the new models' settings. Validation across 2019–2024 selected an EWMA decay of 0.97 and the zero-drift limit of the directional regression (Supplementary Table S26), so the stock and SPY return features did not justify a directional adjustment under this criterion and the selected directional and adaptive forecasts were identical. Testing the frozen models in 2025 supplied 245 five-session origins per ticker, more than fourteen times the 17 available in the 2026 case study, and in both periods central price errors remained close to the unchanged-price benchmark. None of the tested changes repaired the large stock-price misses or gave a consistent central-forecast advantage.

Table 4: Five-session stock forecasts in 2025 and August–September 2026. Each ticker has 245 origins in 2025 and 17 in 2026. MAE scores the forecast median; MAE, CRPS, and central 90% interval width are dollars per share. Scores average dates within each of three 10,000-path replicates and then average replicates. Adaptive denotes the Gaussian model with historically selected EWMA decay 0.97. Historical selection chose zero directional drift, making the selected directional model identical to Adaptive. The unchanged-price benchmark has no uncertainty interval.

Year	Stock	Model	Median MAE	CRPS	Coverage (%)	Width
2025	GS	JumpHMM	22.31	16.22	84.4	84.71
2025	GS	Unchanged	22.61	22.61	–	–
2025	GS	Adaptive	22.62	16.32	89.8	94.86
2025	LLY	JumpHMM	39.10	29.60	69.9	100.40
2025	LLY	Unchanged	39.37	39.37	–	–
2025	LLY	Adaptive	39.35	28.57	84.4	151.37
2026	GS	JumpHMM	16.25	13.03	100.0	129.05
2026	GS	Unchanged	15.51	15.51	–	–
2026	GS	Adaptive	15.48	15.58	100.0	176.18
2026	LLY	JumpHMM	49.44	35.60	70.6	147.26
2026	LLY	Unchanged	49.37	49.37	–	–
2026	LLY	Adaptive	49.31	33.81	94.1	191.38

We then scored the full forecast distributions and found a ticker-dependent benefit from adaptive volatility (Table 4). In 2025, LLY's five-session CRPS fell from 29.60 under JumpHMM to 28.57 under the adaptive model, while central 90% coverage increased from 69.9% to 84.4%. Average interval width increased from \$100.40 to \$151.37, so the coverage gain came with a wider range of predicted prices, and the lower CRPS indicated that this tradeoff improved the distribution score even though coverage remained below its nominal level. The 2026 comparison showed the same direction of change for LLY, with CRPS falling from 35.60 to 33.81 and coverage rising from 70.6% to 94.1%, and the adaptive model had lower date-level CRPS on 131 of 245 LLY origins in 2025 and ten of seventeen in 2026. For GS, however, CRPS increased slightly in 2025, from 16.22 to 16.32, and by 20% in 2026, from 13.03 to 15.58, and although both GS models covered every 2026 endpoint, the adaptive intervals were wider. Mean-based RMSE also remained close to the unchanged-price benchmark, and the selected directional forecasts matched the adaptive forecasts exactly (Supplementary Table S27), while the one-session comparison showed little separation in

central price error from an unchanged-price forecast (Supplementary Table S28). Adaptive volatility therefore improved LLY’s forecast uncertainty, not the prediction of stock-price direction, and we retained JumpHMM as the worked example for the IV framework rather than selecting a replacement stock model from these test outcomes.

Finally, we widened the return-emission bound from $b = 10$ to $b = 20$, repeated the scenario, ablation, forecast, and stock-benchmark simulations, and observed small changes in the reported loss and forecast summaries (Supplementary Tables S30 and S31). Each bound implied state-specific daily return limits (Supplementary Table S29). Widening the bound changed mean terminal short-call P&L by less than \$0.02 per share and its 5% expected shortfall by less than \$0.07 in the fitted illustrations, and at the ten-transition coupled-factor ablation endpoint it changed mean call P&L by less than \$0.004 and expected shortfall by less than \$0.02 (Supplementary Table S30). In the forecast comparisons, five-session coupled option MAE changed by less than \$0.007 per share and the reported stock CRPS values by less than \$0.002 (Supplementary Table S31), so the wider bound did not alter the conclusions of any forecast comparison. These checks compared two specified bounded distributions on the retained simulation ensembles and did not validate either support limit or establish insensitivity to other tail specifications.

4 Discussion

In this study, we developed a framework for examining how IV assumptions affect American-option values while keeping a chosen stock-return model, here JumpHMM, fixed. Repricing identical stock paths under five ways of setting IV, namely holding it fixed at its starting value (frozen IV), setting it each day to the fitted surface’s prediction, moving it partway toward that prediction each day, adding random shocks to that movement, and linking those shocks to stock returns, changed option values before expiration and the outcome of closing short positions early, while starting values and payoffs at expiration agreed exactly, which made the experiment a controlled comparison of the IV assumptions. The pattern of those changes followed from how each option’s implied variance was updated in (14). With $\kappa = 15$ and daily steps, each trading day closed about 6% of the gap between an option’s implied variance and the variance predicted by the fitted surface, so half of any gap remained after about eleven trading days. The version without random shocks therefore lagged behind the moving surface prediction, and after ten trading days its P&L differences from setting IV each day directly to the surface prediction were at least three quarters as large as those of frozen IV (Supplementary Table S13). The random shocks averaged zero, and adding them raised the GS put’s average absolute price difference from prices with IV set directly to the surface prediction from \$0.42 without shocks to \$1.75 with them while changing its average P&L difference by \$0.06, which explains why large price changes on individual paths left average P&L nearly unchanged. Linking the shocks to stock returns with a negative coefficient raised IV after the stock fell and lowered it after the stock rose, the same direction as the leverage effect observed in equity data Cont [2001]. It therefore raised put values on the falling-stock paths where short puts already lost money and lowered call values on the rising-stock paths where short calls lost money, which increased the average loss in the worst 5% of outcomes (expected shortfall) for short puts and reduced it for short calls for both GS and LLY.

The forecast tests asked a separate question, whether the model predicted later market prices, and there the full IV update, with its parameters held fixed, reduced the error of the average option forecast only slightly relative to frozen IV, with no consistent advantage across dates or when forecasts were summarized by the median instead of the mean, while its central 90% price ranges contained every observed GS price but only about two thirds of LLY prices (Table 3). The slow adjustment also limited what the IV update could add over five trading days. Every version started from the IV observed on the forecast date, with each option’s surface prediction rescaled to equal that IV on that date, so gaps opened only as stock moves and the passage of time changed the prediction. The update closed only about a quarter of any such gap in five days, and the changing prediction and the random shocks raised IV on some paths and lowered it on others. Averaged across paths, the updated IV therefore stayed within 0.3 volatility points of its starting value, which frozen IV kept throughout, although individual paths moved about 2.5 points (Supplementary Table S24), so the two average option forecasts could not differ materially. An update with fixed parameters that pulls IV toward a fixed surface carries no information about future IV beyond how the surface prediction changes with moneyness and time to expiration, whereas observed IV surfaces shift in level, skew,

and curvature over time [Cont and da Fonseca \[2002\]](#), so a better forecast would have required an input that tracked the IV level. The framework’s contribution was the ability to compare these assumptions while holding the options, stock paths, and pricing calculation fixed. That control made the measured changes and their limits interpretable, and it kept identical payoffs at expiration from being mistaken for evidence that the simulated IV paths before expiration were realistic. Agreement within the simulator is not agreement with the market, which the comparisons with later option and stock prices tested separately.

The stock forecast tests showed why this distinction mattered for forward use. Repeating the option forecasts with the stock paths that actually occurred cut option errors 3.8- to 5.4-fold on the same options and dates, which identified the stock forecast as the main source of option forecast error, although that information would not have been available when a forecast was made. JumpHMM’s median stock forecasts nearly matched a forecast of no price change because of its drift. We imposed an average log return of 10% a year on JumpHMM, about 0.2% over five trading days, whereas the simulated five-day log return had a standard deviation near 4%, about twenty times larger. The median simulated price therefore rose by an average of only 0.16–0.27% from the starting price (Supplementary Table S24), and its errors nearly matched those of the no-change forecast. Expected returns are small relative to short-horizon return variation, and even a constant expected return can be estimated precisely only from long spans of data [Merton \[1980\]](#). Regressions that predict equity returns have also rarely beaten the historical average out of sample [Welch and Goyal \[2008\]](#), which is consistent with our finding that the simple model predicting direction from recent stock and market returns forecast 2019–2024 prices best with its predicted drift set to zero. These findings concern the specified models and inputs rather than the general possibility of predicting returns. Starting JumpHMM in the hidden state implied by recent returns did not materially improve five-day forecasts either, since the model’s switching between states erased the influence of the starting state within a few days.

The simple model that scaled its forecasts by recent volatility helped LLY but not GS, because volatility, unlike direction, persists enough to be forecast from recent returns [Cont \[2001\]](#), [Andersen and Bollerslev \[1998\]](#) and LLY’s volatility stayed above JumpHMM’s level in both test periods. Because each JumpHMM forecast started from the model’s long-run state probabilities, the width of its forecasts stayed at the volatility of its 2014–2024 fit, whereas the standard deviation of LLY’s daily returns was 1.5 times that level in 2025 and 1.3 times in August and September 2026 (Supplementary Table S24). The adaptive model’s volatility, an exponentially weighted moving average (EWMA) of recent squared returns, tracked those levels and widened LLY’s forecast ranges toward the observed spread of outcomes. That improved LLY’s continuous ranked probability score (CRPS), which rewards forecast distributions concentrated near the observed outcome, in both periods, although its 90% ranges still contained fewer than 90% of the 2025 outcomes. GS’s 2025 daily volatility was within 10% of the JumpHMM level, so adapting it changed the score little. In August and September 2026, the standard deviation of GS’s daily returns was 1.40%, below both the 1.80% JumpHMM level and the adaptive estimate, which April–July returns had raised to an average of 2.26%. The 90% ranges of both models already contained every 2026 GS outcome, so the adaptive model’s wider ranges made its forecasts less precise without making them more reliable, a trade that CRPS penalizes [Gneiting et al. \[2007\]](#). The evidence therefore supported widening forecast ranges for a ticker whose recent volatility exceeded JumpHMM’s level, not replacing the stock model or using its median forecasts as predictions of direction, and we retained JumpHMM as the example stock model and reported the two simpler models as comparisons.

Separating the stock model from the IV model also left requirements that forecast comparisons could not address. A binomial tree handles early exercise for each option separately but does not make prices consistent across strikes, and the GS prices that violated no-arbitrage conditions across strikes showed this limitation even when IV was set directly from the fitted surface (Supplementary Table S15). For a strategy that holds several options, those inconsistencies matter because decisions depend on relative prices as well as the value of each position, and surface methods that impose no-arbitrage constraints offer one way to meet that requirement before simulated prices are used in place of market data [Cont and Vuletić \[2023\]](#). Fitting the surfaces posed a second problem. The neural surfaces fitted IV more closely than the parametric surface across all observations, yet on May 11, one of the dates used for fitting, they overpredicted near-the-money IV for MSFT and LLY, and the surface fitted on 68 trading days through July 31 showed a related error on later dates. Daily errors showed that LLY’s overprediction on later dates began after a scheduled earnings report.

The surface fitted through July underpredicted LLY’s IV by 17.90 volatility points on August 4, the trading day before the August 5 report, and overpredicted it by 2.04 to 8.07 points on every observed day from August 6 through September 4 (Supplementary Table S24), the rise before and fall after an anticipated announcement that option prices have long shown [Patell and Wolfson \[1979\]](#), [Dubinsky et al. \[2019\]](#). Each ticker’s fitted IV level averaged over the fitting period, so it could not represent IV both before and after a report, whereas GS, whose July 14 report lay inside the fitting period and whose next report came after the test period, had daily errors between -3.07 and 3.59 points on later dates. The May 11 errors fit the same explanation, since MSFT and LLY, the two tickers whose IV the surfaces overpredicted, reported on April 29 and April 30, after ten of the fifteen fitting days (Supplementary Table S5). Adding the time to scheduled earnings reports as a surface input reduced error when surfaces fitted on earlier April dates were tested on April 23 and 24 (Table 2), but the surface fitted through July used only moneyness and time to expiration, and fitting it on more dates gave it no way to update a ticker’s IV level. In the forecast tests, rescaling the surface to the IV observed on each forecast date removed the starting level error, but it was an explicit change to the starting values and did not make prices consistent across options. Pricing each option with the IV that Alpaca, the data vendor, reported on the forecast’s end date reduced errors further, although it again used information from that later date, and agreement with Alpaca’s indicative bid and ask did not establish agreement with exchange quotes or show that Alpaca’s Black–Scholes IV always reproduces prices in an American binomial tree. Accurate IV surfaces, accurate stock forecasts, accurate option prices, and prices consistent across strikes therefore remained separate requirements, and meeting one did not establish the others or make the framework a joint pricing model of the stock and its volatility.

The evidence is limited by the data source, the observation windows, and the scope of model selection. All option observations came from Alpaca’s free indicative feed, whose quotes are derived from exchange quotes rather than copied from them, which supported comparisons with the captured vendor data but not claims about prices at which trades could execute, and the download times did not establish that stock and option prices were recorded at the same moment. The first surface comparisons used fifteen daily snapshots, and the later-date tests trained each network with a single random seed. The option forecast test covered 23 trading days, and the 2025 test covered stock forecasts only. Overlapping forecast periods and shared market moves reduced the independent information in both tests, which more simulated paths could not restore. Because the data collection kept only certain expiration ranges each day, the one-month options first selected for the forecast tests had no quotes five trading days later, so the shorter-dated options added afterward did not validate the one-month simulation examples. We proposed the two simpler stock models after seeing the August and September 2026 forecast misses, although earlier data chose their settings, and the few return inputs and settings we tested support no general claim that one model is better. The earnings explanation of the surface errors rested on a few report dates for three tickers and was not tested by refitting the July surface with earnings inputs. JumpHMM’s fitted parameters and the parameters of the IV update, including its link to stock returns, stayed fixed, and two proposed extensions that would let the IV level depend on JumpHMM’s hidden state and its visits to the states that produce extreme returns were switched off. Capping JumpHMM’s heavy-tailed daily returns at ten times each state’s fitted return scale gave simulated prices a finite mean and variance, but neither that cap nor the wider cap tested for sensitivity was shown to match the largest real stock moves. The check across strikes used a finite set of strikes and did not test consistency across expiration dates or over time, and valuation omitted dividends, execution costs, margin, premium financing, hedging, and early assignment before the end of the horizon. These limits restrict the present use of the framework to controlled modeling comparisons and the specific forecasting evidence reported here. Complete daily histories of the same options, collected across different market conditions, would allow the forecast tests to be repeated on one-month options and the switched-off extensions to be evaluated, and that evaluation should precede conclusions about practical trading use.

5 Conclusion

In this study, we built a simulator that values American options along stock paths from a separately chosen stock model, here the jump hidden Markov model JumpHMM, by updating each option’s IV on every simulated date. Each option’s implied variance moved partway each day toward the prediction of a neural surface fitted to past quotes, following the mean-reverting variance equation of the Heston model with random shocks, and a binomial tree converted the resulting IV into the

option's price. More flexible surfaces, fitted separately to smaller groups of tickers, matched the fitting data more closely, but their accuracy on later dates was uneven. Repricing identical stock paths under different IV updates changed option values before expiration and the outcome of closing positions early, while payoffs at expiration stayed the same. In forecasts of later option prices, the IV update with random shocks linked to stock returns showed no consistent advantage over holding IV fixed. Repeating the forecasts with the stock paths that actually occurred, information not available when forecasting, reduced option errors, which motivated a separate test of the stock forecasts. In stock forecasts for 2025 and for August and September 2026, JumpHMM and two simpler stock models predicted prices about as accurately as assuming no change. The simpler model whose volatility adapted to recent returns improved the predicted range of stock prices for LLY in both periods but not for GS, and tests on 2019–2024 data found no benefit from predicting direction with recent stock and market returns. These findings support the framework as a reproducible way to compare IV and stock assumptions, while limiting claims about its forecasting accuracy. JumpHMM remains the example stock model, and we did not replace it with either simpler model. Saved observations, fitted models, simulation outputs, and scoring code make the comparisons reviewable. Incomplete histories of one-month options, overlapping evaluation dates, the small set of models compared, and remaining price inconsistencies across strikes limit broader use.

A Interpretation of the Contract Variance Factor

The scenario model assigned a variance state to each contract rather than one instantaneous variance state to the underlying. The following continuous-time process motivated the Euler update for a fixed target:

$$dv_{a,t} = \kappa(\bar{v}_{a,t} - v_{a,t}) dt + \sigma_v \sqrt{v_{a,t}} dW_{a,t}. \quad (20)$$

Contract a indexes ticker, strike, and expiration. The target $\bar{v}_{a,t}$ in (9) changes with current money-ness and calendar DTE. If that target were held fixed and a stationary distribution existed, its mean would equal $\bar{v}_a$. In the implemented scenario, however, the target moved at every trading date and the hard floor in (14) altered the unconstrained square-root process. We therefore use the stationary result only as motivation for mean reversion, not as a claim about the simulated distribution. At entry, $v_{a,0} = \bar{v}_{a,0}$ reproduces the fitted IV product exactly. Thereafter, $\sigma_{a,t}^2 = v_{a,t}$ supplies the lattice input. The fitted level and neural shape are not separately identified: shifting a constant between $\ln \theta_i$ and the network output bias leaves $\theta_i \psi_i$ unchanged. This does not change fitted IV or scenario output, but it prevents separate economic interpretation of the two components.

The forward simulation for the fitted illustrations drew the stock paths first, standardized their one-session log returns across the completed ensemble, and then priced each contract and advanced its factor at every trading transition before replacing the final mark with intrinsic value (Algorithm S1). The paired ablation followed the same steps but replaced the ensemble standardization with constants frozen from an independent pilot simulation.

Algorithm S1 Forward simulation of contract values

Require: JumpHMM marginal; fitted (θ_i, ψ_i) ; contract (K, T) ; trading dates $d_0, \dots, d_L$; calendar DTE $\tau_0, \dots, \tau_L$; (κ, σ_v, ρ) ; S_0 ; r ; N_p paths; LR depth N_{LR} .

Ensure: Stock, variance, IV, and option-value paths.

- 1: Draw N_p JumpHMM stock paths with L trading transitions and emissions truncated as in (2).
 - 2: Compute $Z_{j,\ell}^S$ by standardizing all simulated one-session log returns as in (12).
 - 3: Draw $Z_{j,\ell}^\perp \sim \mathcal{N}(0, 1)$ once per path and transition; set $Z_{j,\ell}^v \leftarrow \rho Z_{j,\ell}^S + \sqrt{1 - \rho^2} Z_{j,\ell}^\perp$ and reuse it for every contract.
 - 4: **for** contract a and path j **do**
 - 5: $v_{a,0}^{(j)} \leftarrow \theta_i \psi_i(\tau_0, K/S_0)$
 - 6: **for** $\ell = 0$ **to** $L - 1$ **do**
 - 7: $\sigma_{a,\ell}^{(j)} \leftarrow \sqrt{v_{a,\ell}^{(j)}}$
 - 8: $P_{a,\ell}^{(j)} \leftarrow \text{LR}_{N_{LR}}(S_{j,\ell}, K, \sigma_{a,\ell}^{(j)}, \tau_\ell/365, r)$
 - 9: $\bar{v}_{a,\ell}^{(j)} \leftarrow \theta_i \psi_i(\tau_\ell, K/S_{j,\ell})$
 - 10: Update $v_{a,\ell+1}^{(j)}$ with the hard-floor rule in (14) using $\Delta t = 1/252$.
 - 11: **end for**
 - 12: $P_{a,L}^{(j)} \leftarrow \max\{\phi(S_{j,L} - K), 0\}$, where $\phi = 1$ for a call and $\phi = -1$ for a put.
 - 13: **end for**
 - 14: **return** all paths.
-

B Calibration Details

The snapshot labels, capture timestamps, and underlying-session dates did not always coincide. Table S1 preserves these fields for the frozen corpus described in the main Results. All dates are in 2026. The May 11 underlying-session snapshot was captured on May 12. Temporal earnings splits followed snapshot-directory labels, and the May 11 holdout followed the underlying-session date. The first snapshot contained 23 tickers and the remaining snapshots contained 31. The [source repository](#) provides experiment drivers and reproduction instructions. Its frozen corpus manifest records each file’s SHA-256 hash and filtered row count. Saved ablation outputs also include pilot constants, path-level marks, numerical audits, and copies of the computational sources so that the reported comparisons can be traced to their inputs.

Table S1: Frozen corpus provenance. Temporal earnings splits used snapshot labels; the May 11 single-date holdout used the underlying-session field. The first snapshot label is April 14 although its underlying close was from April 13.

Snapshot label	Capture date	Underlying session	Rows
04-14-2026	2026-04-14	2026-04-13	18,250

Table S2: Sector partition of the 31-ticker ladder across fifteen snapshots. Counts are filtered observations used in calibration.

Sector	Observations	Tickers
ETF	102,738	IWM, QQQ, SPY
Technology	68,334	AAPL, AMD, AVGO, GOOG, INTC, META, MSFT, MU, NVDA, QCOM
Healthcare	26,387	ABBV, AMGN, BMY, JNJ, LLY, MRNA, PFE, UNH
Financials	17,938	BAC, GS, JPM, WFC
Retail	11,320	TGT, UPS, WMT
Energy	7,832	CVX, OXY, XOM

Table S3: In-sample RMSE by sector, in volatility percentage points. The sector network improved on the global neural network in every group, while technology and healthcare retained the largest errors.

Sector	Parametric	Global NN	Sector NN	Observations
ETF	10.54	8.69	6.10	102,738
Financials	9.05	7.79	6.70	17,938
Energy	9.36	8.24	7.88	7,832
Retail	11.73	10.23	9.50	11,320
Healthcare	13.49	12.71	12.53	26,387
Technology	15.58	15.31	14.47	68,334

Table S4: Largest per-ticker in-sample RMSE reductions among the 29 qualified tickers. In total, 21 qualified tickers improved and eight worsened; the combined per-ticker-plus-fallback model reduced pooled RMSE from 10.24 to 9.73 volatility percentage points. The BMY and PFE fits retained their sector surfaces.

Ticker	Observations	Sector NN	Per-ticker NN	Reduction
JNJ	2,190	11.14	7.17	3.97
MRNA	2,851	17.49	13.74	3.76
AAPL	6,594	14.30	12.59	1.70
INTC	3,417	17.78	16.29	1.49
AMGN	3,383	13.36	12.14	1.21
MU	6,619	18.45	17.26	1.19
NVDA	5,805	10.14	9.15	0.99

Table S5: Mean IV near the money in the May 11 smile panels (Fig. 1). Each row uses the plotted calls and puts with $0.98 \leq K/S \leq 1.02$ at the indicated calendar days to expiry (DTE). Observed and predicted IV are percentages; bias is mean per-ticker predicted IV minus observed IV in percentage points. Predictions use the saved fifteen-date fit evaluated at each observed contract. The NVDA subset contains only two observations. The public earnings calendar dated GS, MSFT, and LLY reports on April 13, April 29, and April 30, 2026, within the calibration window.

Ticker	DTE	N	Observed IV	Predicted IV	Bias
SPY	7	52	13.57	13.75	+0.18
NVDA	7	2	38.65	34.02	-4.62
MSFT	9	14	28.47	37.92	+9.45
LLY	11	20	38.59	46.49	+7.90
GS	11	24	32.06	31.74	-0.32
AVGO	9	14	49.08	43.72	-5.37

Table S6: May 11 price-error summary for the contracts plotted in Fig. 2. Dollar errors are absolute differences from the market mid. The per-ticker column used a per-ticker surface where qualified and a sector fallback otherwise; the market-IV reference passed each contract's reported IV to the same 200-step CRR lattice.

Ticker	DTE	N	Half-spread	Per-ticker error	Inside spread	Market-IV error
SPY	7	176	\$0.03	\$0.12	33%	\$0.01
NVDA	7	34	\$0.04	\$0.13	35%	\$0.12
LLY	11	156	\$2.98	\$4.01	30%	\$0.67
GS	11	145	\$1.56	\$0.46	88%	\$0.12

Table S7: Best and worst ticker-level in-sample RMSE under the sector networks. Errors are in volatility percentage points.

Rank	Ticker	Observations	RMSE	Sector
<i>Best five</i>				
1	GS	8,772	5.40	Financials
2	SPY	42,224	6.02	ETF
3	IWM	21,368	6.11	ETF
4	QQQ	39,146	6.17	ETF
5	JPM	3,720	6.18	Financials
<i>Worst five</i>				
27	PFE	1,300	17.66	Healthcare
28	AMD	4,566	17.74	Technology
29	INTC	3,417	17.78	Technology
30	MU	6,619	18.45	Technology
31	QCOM	3,375	21.46	Technology

B.1 Single-date holdout

We held out May 11, 2026, to examine whether the sector surfaces transferred to a nearby date within the observed period. We retrained on the other fourteen dates and calculated input-standardization constants from those training rows alone. Pooled test error exceeded training error by 0.68 volatility percentage points (Table S8). Energy and retail had larger positive gaps, indicating poorer transfer for those groups in this split. The pooled result therefore concealed differences in performance across sectors. This analysis used one held-out date and one training seed. It described transfer within the available observation window and did not test stability across repeated training runs or different market regimes.

Table S8: Sector-network RMSE after fitting on fourteen dates and holding out the 14,442 observations from May 11, 2026. Values and test-minus-train gaps are in volatility percentage points.

Sector	Train	Test	Gap
ETF	6.12	5.87	−0.25
Financials	6.72	6.32	−0.40
Healthcare	12.58	12.00	−0.58
Technology	14.45	15.04	+0.58
Energy	7.74	9.97	+2.23
Retail	9.21	13.17	+3.96
Pooled	10.21	10.89	+0.68

C Earnings-Holdout Ticker Results

The technology-ticker breakdown examined whether the pooled improvement from earnings inputs extended across individual tickers. The two-input and four-input models used the same training and test observations. Several tickers with a peer earnings date near the holdout had lower error under the four-input model (Table S9). The improvement was uneven, and INTC and NVDA had higher errors. This pattern was consistent with useful calendar information in the pooled fit. Both ticker and peer distances were added together, so the comparison did not isolate the contribution of either input. Calendar distance also contained no information about the sign or magnitude of a realized earnings surprise. The ticker results therefore described variation within this particular temporal split.

Table S9: Technology-ticker test RMSE for the pooled model (A) and earnings-aware model (C). Inputs e and e^{peer} are median signed ticker distance and minimum peer distance, in days. Error differences are in volatility percentage points.

Ticker	e	e^{peer}	A: pooled	C: event inputs	Difference
QCOM	+5	1	41.66	37.59	−4.07
AMD	+11	1	40.07	36.50	−3.57
META	+5	1	14.32	10.73	−3.59
MSFT	+5	1	14.00	10.73	−3.28
GOOG	+5	1	9.87	7.90	−1.97
MU	−30	1	16.95	15.59	−1.36
AAPL	+6	1	10.42	10.34	−0.08
AVGO	+30	1	12.58	12.83	+0.24
NVDA	+26	1	9.43	10.47	+1.05
INTC	−1	5	33.17	35.94	+2.77

D Scenario Statistics and Greeks

The fitted illustrations used a common simulation design to compare contract outcomes under two stock-return marginals (Table S10). For GS, frequent retention of the entry premium coexisted with substantial lower-tail losses (Table S11). The 5% expected shortfall summarized those losses as the mean P&L at or below the empirical 5% quantile. More negative values indicated worse simulated tails. The premium-retained interval was a two-sided 95% Wilson interval for the fraction of paths that expired out of the money. That interval described sampling uncertainty in the simulated frequency conditional on the chosen return model. It did not measure uncertainty in the fitted return distribution or the accuracy of the simulation against future market outcomes.

Table S10: Fixed simulation design shared by the GS and LLY fitted illustrations.

Setting	Value
Simulation paths	1,000
Random seed	20260429
Horizon	April 28–May 29, 2026
Calendar days	31
Trading transitions	22
Annual mean-growth prior	10%
Mean-reversion rate κ	15
Factor volatility σ_v	0.5
Return–factor coupling ρ	−0.6
Risk-free rate r	4.25%
Dividend yield q	0
Leisen–Reimer depth	201

Table S11: Scenario results for GS from 1,000 paths between April 28 and May 29, 2026. The horizon had 31 calendar days and 22 trading transitions. Dollar option values and P&L are per share.

Statistic	Short put	Short call
Initial spot	926.38	
Strike	890.00	970.00
Market delta	-0.295	+0.328
Market IV	31.2%	28.9%
Market mid	16.51	16.09
Model entry value	17.26	16.07
Model value minus market mid	0.75	-0.02
Mean P&L	4.30	-2.19
Monte Carlo SE of mean	0.89	1.23
Median P&L	16.51	16.09
Standard deviation	28.01	38.87
5% quantile	-58.96	-86.18
5% expected shortfall	-92.15	-130.77
Premium retained	74.0%	67.7%
Wilson 95% interval	71.2–76.6%	64.7–70.5%
Delta-heuristic premium retained	70.5%	67.2%
Simulated minus heuristic	+3.5 pp	+0.5 pp

We calculated Greeks along each path to describe how interim option values responded to changes in pricing inputs. The calculation used central finite differences of the same Leisen–Reimer function that supplied the base mark (Algorithm S2). Delta measured price sensitivity to spot, and gamma measured the change in delta with spot. Vega measured sensitivity to volatility and was reported per one volatility percentage point. The GS paths showed delta approaching the terminal exercise states, gamma concentrating near the strike, and Vega declining toward zero (Fig. S1). These sensitivities used the long-option convention. The corresponding short-position Greeks had the opposite sign because the short seller owed the option value.

Algorithm S2 Path-conditional Greeks by central finite differences

Require: State (S, σ, τ) ; contract (K, r) ; LR depth N_{LR} ; relative spot bump h_S ; absolute IV bump h_σ .

Ensure: Δ , Γ , and Vega.

- 1: $P_+^S \leftarrow \text{LR}(S(1 + h_S), K, \sigma, \tau, r)$ and $P_-^S \leftarrow \text{LR}(S(1 - h_S), K, \sigma, \tau, r)$.
 - 2: $P_0 \leftarrow \text{LR}(S, K, \sigma, \tau, r)$.
 - 3: $P_+^\sigma \leftarrow \text{LR}(S, K, \sigma + h_\sigma, \tau, r)$ and $P_-^\sigma \leftarrow \text{LR}(S, K, \sigma - h_\sigma, \tau, r)$.
 - 4: $\Delta \leftarrow (P_+^S - P_-^S)/(2h_S S)$.
 - 5: $\Gamma \leftarrow (P_+^S - 2P_0 + P_-^S)/(h_S S)^2$.
 - 6: $\text{Vega} \leftarrow 0.01(P_+^\sigma - P_-^\sigma)/(2h_\sigma)$.
 - 7: **return** $(\Delta, \Gamma, \text{Vega})$.
-

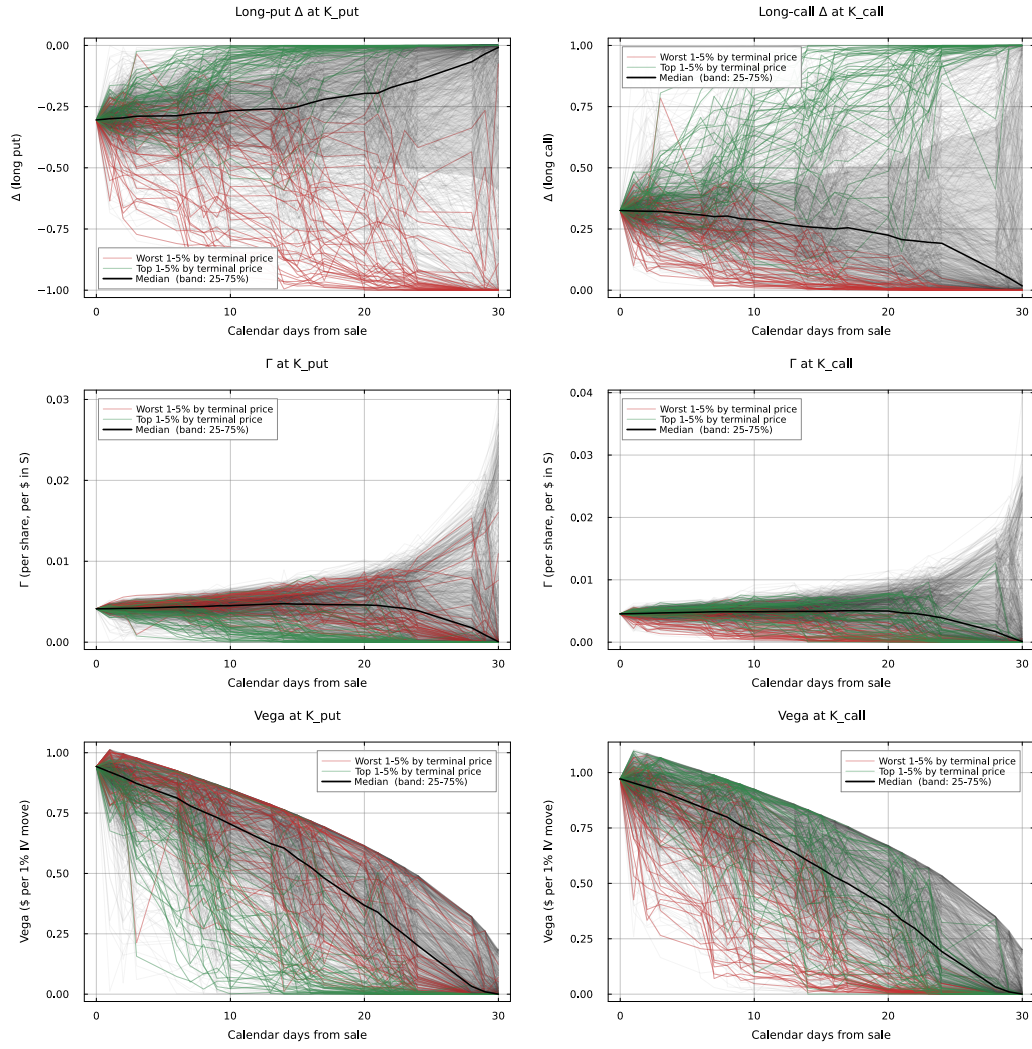

Figure S1: Simulated evolution of GS long-option delta, gamma, and Vega along the stock paths. Sensitivities are calculated with the 201-step Leisen-Reimer pricer. Spot bumps were 1.5% of spot, and IV bumps were 0.005. Vega is dollars per one volatility percentage point.

Table S12: Scenario results for LLY from 1,000 paths between April 28 and May 29, 2026. The horizon had 31 calendar days and 22 trading transitions. Dollar option values and P&L are per share.

Statistic	Short put	Short call
Initial spot	873.83	
Strike	825.00	940.00
Market delta	-0.303	+0.309
Market IV	44.4%	44.0%
Market mid	23.30	20.76
Model entry value	21.95	18.96
Model value minus market mid	-1.35	-1.80
Mean P&L	16.39	10.61
Monte Carlo SE of mean	0.63	0.91
Median P&L	23.30	20.76
Standard deviation	19.86	28.66
5% quantile	-27.91	-51.96
5% expected shortfall	-56.84	-94.18
Premium retained	80.7%	79.3%
Wilson 95% interval	78.1–83.0%	76.7–81.7%
Delta-heuristic premium retained	69.7%	69.1%
Simulated minus heuristic	+11.0 pp	+10.2 pp

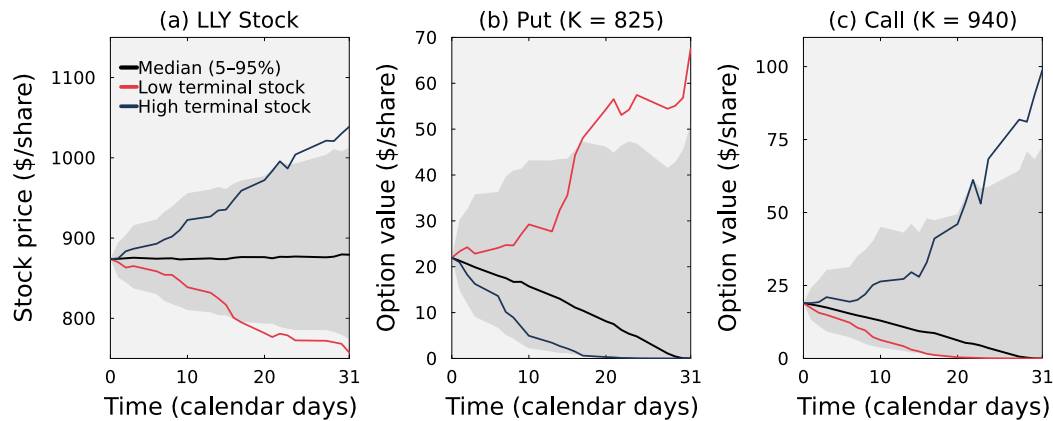

Figure S2: Simulated evolution of LLY stock prices (a), put values (b), and call values (c) along 1,000 paths between April 28 and May 29, 2026. The fitted surfaces included observations from this scenario period; these are illustrative paths, not an out-of-sample forecast. Time is measured in calendar days from April 28. Black curves show pointwise medians, and shading contains the middle 90% of values. Red and blue curves show group medians for the 1st–5th and 95th–99th terminal-stock percentiles. Option values are dollars per share and represent repurchase costs for a short seller. Entry premiums were \$23.30 per share for the put and \$20.76 for the call.

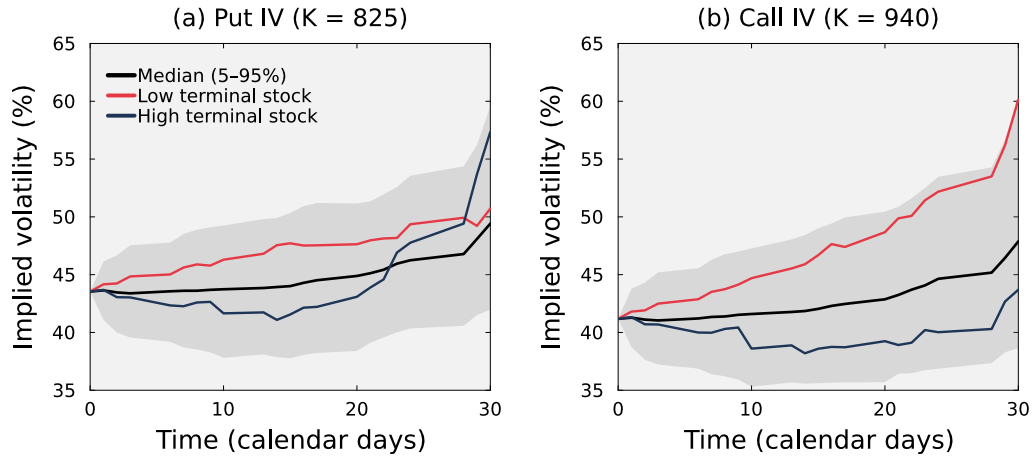

Figure S3: Simulated evolution of annualized IV at the LLY put strike (a) and call strike (b). Both panels express IV as percentages on the same vertical scale. Curves show pointwise medians across all 1,000 paths and within the terminal-stock groups in Supplementary Fig. S2; shading shows the 5th–95th percentile band. Time is measured in calendar days from April 28, 2026, and stops before expiration, when IV no longer enters the payoff.

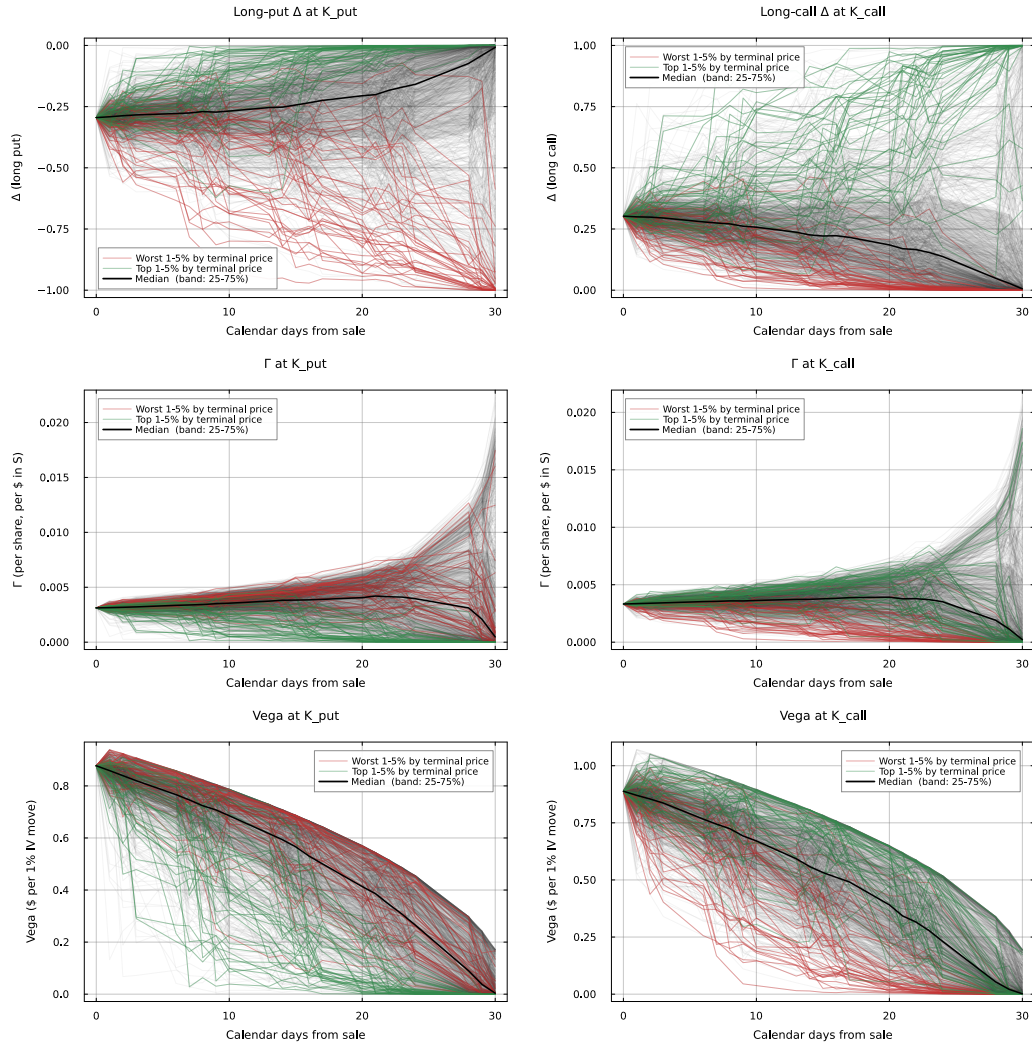

Figure S4: Simulated evolution of LLY long-option delta, gamma, and Vega along the stock paths. Sensitivities are calculated with the 201-step Leisen-Reimer pricer. Short-position Greeks have the opposite sign.

E Dynamic Ablation and Strike Diagnostics

The primary ten-transition endpoint compared liquidation outcomes across IV variants on shared stock paths (Table S13). Mean absolute mark differences measured how much the prices changed along individual paths. Paired mean P&L differences showed how those changes combined across the ensemble. The three evaluation seeds provided separate realizations of the comparison under the same fitted models and pilot constants (Table S14). Expected shortfalls summarized the simulated lower tails of P&L. The paired standard errors applied to mean differences and did not supply uncertainty intervals for expected shortfall. All reported uncertainty was conditional on the fitted surface and pilot normalization constants. Variation from refitting either component remained outside these estimates.

Table S13: Liquidation after ten trading transitions (May 12, 2026), with 17 calendar DTE. Each row uses 3,000 paths. All monetary quantities are dollars per share. $\Delta P\&L$ and mean $|\Delta P|$ compare the variant with the direct-surface reference on identical paths. Parentheses contain the paired Monte Carlo standard error of mean $\Delta P\&L$. More negative 5% expected shortfall indicates a worse simulated lower tail.

Contract	IV variant	Mean P&L	ES _{5%}	$\Delta P\&L$ (SE)	Mean $ \Delta P $
GS put	Frozen IV	0.67	-63.08	+0.28 (0.01)	0.51

LLY call	20260431	2.37	+2.12	0.07

Table S15 reports the necessary strike-condition checks at 401 steps. The grid had eleven fixed strikes at the scenario expiry, with fifty stock paths evaluated after ten and twenty transitions plus one shared entry state. As spot moved, some fixed strikes left the calibration moneyness interval; the audit therefore included extrapolated states. Each variant and ticker supplied 2,222 bound checks, 2,020 adjacent-strike checks, and 1,818 convexity checks across calls and puts. The companion machine-readable output reports both lattice depths, each test location, and the violation magnitude. Passing this finite grid does not establish the absence of arbitrage elsewhere or consistency across maturities.

Table S15: Strike-condition violations exceeding \$0.01 per share at 401 lattice steps. Entries show violations/tests. Vertical denotes the upper bound on an adjacent-strike option-price difference. Max reports the largest positive deviation across the four checks, including deviations below the reporting tolerance.

Ticker	Variant	Bounds	Monotonicity	Vertical	Convexity	Max (\$)
GS	Frozen IV	0/2222	0/2020	0/2020	0/1818	0.008
GS	Direct surface	0/2222	68/2020	68/2020	178/1818	0.113

F Chronological Evaluation Details

The completed expanding-window experiment tested conditional surface transfer across 53 successive capture-date splits. Its two-input sector networks used moneyness and maturity from each later observation, including that observation’s stock price. Table S16 reports the distribution of fold RMSE by test month. The new July-cutoff experiment used a larger training window, stricter capture handling, recomputed calendar DTE, and a later test period. Its pooled sector errors are reported separately in Table S17, so they are not interpreted as a paired comparison with the earlier folds. Both analyses used one fixed neural training seed and did not quantify uncertainty from refitting with other seeds.

Table S16: Chronological sector-surface prediction errors across 53 expanding-window folds. Each fold fitted earlier capture dates and evaluated the next captured date using its observed stock price. RMSE is in IV percentage points.

Test month	Folds	Median RMSE	Minimum	Maximum
April	6	12.72	7.79	17.45
May	17	9.62	8.65	11.30
June	18	10.02	8.55	19.25
July	12	9.76	7.68	10.51

Table S17: Training and held-out IV errors for sector surfaces frozen at the July 31 cutoff. Training used 68 underlying sessions; testing used 23 later sessions from August 4 through September 4. Each RMSE pools observations within the indicated sector. Bias is predicted minus observed IV, in percentage points.

Sector	Train rows	Test rows	Train RMSE	Test RMSE	Test bias
ETF	503,487	186,987	7.03	6.59	+3.08
Financials	83,005	27,853	7.40	7.81	+2.50
Energy	34,817	10,956	8.15	9.40	+2.45
Retail	50,776	15,096	10.02	11.77	+1.83
Healthcare	126,818	45,472	12.14	12.21	+3.77
Tech	374,635	138,697	14.70	22.91	+14.81
Pooled	1,173,538	425,061	10.79	14.75	+6.88

The origin rule selected contracts before looking for later matches. Table S18 distinguishes selected forecasts whose endpoint fell inside the fixed window from those with valid exact-symbol endpoint quotes. The monthly cohort used 25–45 calendar DTE and selected expiry nearest 31 DTE. The short cohort used 10–21 DTE and selected expiry nearest 14 DTE after the monthly cohort proved unavailable at the five-session horizon. Missing endpoint quotes were not replaced, and coverage of the selected universe remained part of the reported result. Full stock-path availability required a recorded underlying close at every intervening exchange session; it was more restrictive than having an endpoint quote. The observed-stock diagnostic therefore had its own sample size and was compared across IV variants only on that common subset.

Table S18: Availability of exact-contract outcomes by cohort, ticker, and horizon. Selected counts include all origin-selected contracts whose endpoint fell within the fixed window, including endpoints on missing capture dates. Full stock path counts selected contracts with all intervening stock observations, whether or not the endpoint option quote was available. Horizons are exchange sessions.

Cohort	Ticker	Horizon	Origins	Selected	Matched	Missing	Full stock path
monthly	GS	1	22	44	34	10	42
monthly	GS	5	18	36	0	36	26
monthly	LLY	1	22	44	34	10	42
monthly	LLY	5	18	36	0	36	26
short	GS	1	22	44	42	2	42
short	GS	5	18	36	34	2	26
short	LLY	1	22	44	41	3	42
short	LLY	5	18	36	30	6	26

Table S19: One-session option forecasts for the monthly cohort. Scores first average matched contracts within each ticker and origin and then average dates. MAE, CRPS, and central 90% interval width are dollars per share. Coverage averages the within-origin fraction of observed midpoints inside that interval across dates.

Ticker	IV variant	Dates	Quotes	MAE	CRPS	Coverage (%)	Width
GS	Frozen IV	17	34	3.80	2.65	85.3	15.15
GS	Direct surface	17	34	3.79	2.66	82.4	14.68
GS	Mean reversion	17	34	3.80	2.65	85.3	15.15
GS	Uncoupled factor	17	34	3.80	2.65	88.2	16.05
GS	Coupled factor	17	34	3.79	2.65	94.1	15.64
LLY	Frozen IV	17	34	6.11	4.52	76.5	17.32
LLY	Direct surface	17	34	6.16	4.52	76.5	17.55
LLY	Mean reversion	17	34	6.11	4.52	76.5	17.32
LLY	Uncoupled factor	17	34	6.11	4.48	73.5	18.24
LLY	Coupled factor	17	34	6.08	4.51	73.5	17.71

Table S20: Five-session IV-factor diagnostic conditional on the observed stock path for the shorter-maturity cohort. These values use realized stock information and are not joint stock–option forecasts. All variants use the same complete-path subset. Monetary quantities and aggregation follow Table 3.

Ticker	IV variant	Dates	Quotes	MAE	CRPS	Coverage (%)	Width
GS	Frozen IV	13	26	1.07	1.07	0.0	0.00
GS	Direct surface	13	26	1.45	1.45	0.0	0.00
GS	Mean reversion	13	26	1.08	1.08	0.0	0.00
GS	Uncoupled factor	13	26	1.07	0.71	92.3	3.37
GS	Coupled factor	13	26	1.23	0.90	50.0	2.72
LLY	Frozen IV	13	24	1.74	1.74	0.0	0.00
LLY	Direct surface	13	24	2.25	2.25	0.0	0.00
LLY	Mean reversion	13	24	1.74	1.74	0.0	0.00
LLY	Uncoupled factor	13	24	1.73	1.35	84.6	4.40
LLY	Coupled factor	13	24	1.95	1.53	65.4	3.54

Table S21: Stock forecast scores at the observed endpoint dates for the original 1,000-path forecasts. MAE scores forecast means. The random walk has zero log drift and the fixed pilot’s one-session return standard deviation. Monetary errors are dollars per share, and coverage refers to central 90% forecast intervals.

Ticker	Horizon	Stock model	Dates	MAE	CRPS	Coverage (%)
GS	1	JumpHMM	21	10.91	8.06	90.5
GS	1	Random walk	21	10.69	8.25	95.2

LLY	1	Random walk	21	18.87	14.40	76.2
LLY	5	JumpHMM	17	49.83	35.71	70.6
LLY	5	Random walk	17	48.64	34.33	70.6

Table S22: American-lattice repricing with the endpoint’s reported IV for matched contracts with valid reported IV. This diagnostic uses information observed at the endpoint and is not a forecast. MAE is dollars per share; inside-spread frequencies compare the resulting price directly with Alpaca’s indicative bid and ask.

Cohort	Ticker	Horizon	Dates	Quotes	MAE	Inside spread (%)
monthly	GS	1	17	34	0.24	97.1
monthly	LLY	1	17	34	0.46	100.0
short	GS	1	21	42	0.16	100.0
short	GS	5	17	34	0.14	100.0
short	LLY	1	21	41	0.32	100.0
short	LLY	5	17	30	0.34	100.0

Table S23: Five-session option errors under mean and median point forecasts for the shorter-maturity cohort. Mean MAE and Mean RMSE score the simulated mean; Median MAE scores the median. All errors are dollars per share and use the same date-weighted contracts as Table 3. The prespecified mean-based comparison is retained alongside the additional point summaries.

Stock	IV variant	Mean MAE	Median MAE	Mean RMSE
GS	Frozen IV	4.21	2.48	5.06
GS	Direct surface	4.86	2.62	5.62
GS	Mean reversion	4.26	2.50	5.10
GS	Uncoupled factor	4.24	2.48	5.08
GS	Coupled factor	4.19	2.48	4.99
LLY	Frozen IV	11.62	11.78	15.00
LLY	Direct surface	11.62	11.59	14.74
LLY	Mean reversion	11.62	11.77	14.98
LLY	Uncoupled factor	11.61	11.80	14.97
LLY	Coupled factor	11.59	11.79	14.92

We checked numerical calculations separately from agreement with market observations. Recomputing prices from the saved stock and variance paths reproduced the forecast means, quantiles, and CRPS. Increasing lattice depth from 201 to 401 steps in the sampled checks changed prices by at most \$0.0026 per share. At the first origin for each ticker, paired Monte Carlo standard errors for coupled-minus-frozen mean prices ranged from \$0.041 to \$0.061 across the four shorter-maturity five-session contracts. These errors described simulation precision for individual price differences; they were not confidence intervals for average forecast accuracy across market dates. The small aggregate MAE reductions therefore did not justify a claim of predictive superiority. In the observed-stock diagnostic, frozen IV, direct surface evaluation, and deterministic mean reversion produced a single price once the stock path was supplied, so their central intervals had zero width. Stochastic-factor intervals retained only IV uncertainty. Their coverage in Table S20 consequently answered a different question from coverage of the joint stock–option forecasts. The saved score files include both cohorts, both horizons where outcomes were available, all five IV variants, and the date-level errors used in aggregation.

We summarized the quantities behind these forecast outcomes in Table S24. With $\kappa = 15$ and $\Delta t = 1/252$, the Euler update in (14) retained a fraction $1 - \kappa\Delta t \approx 0.94$ of a factor’s deterministic gap to a fixed target at each session. This gave a half-life of 11.3 sessions and closed 26.4% of the gap after five sessions and 45.9% after ten. The five-session rows used the seventeen scored origins per ticker and the matched contracts in Table 3. Their IV changes compared simulated IV five sessions after origin with the observed origin IV, averaging over paths and then contracts. The one-session volatility rows used the stock-benchmark origins in Table 4. Realized values were sample standard deviations of the observed one-session log returns, and EWMA values averaged the adaptive model’s origin estimates. The GS EWMA estimate began from its 2014–2024 sample variance and rose through the April–July 2026 returns before the first August origin. The surface-bias rows repeated the held-out ticker bias in Table S17 by underlying session. The public earnings

calendar dated LLY’s report on August 5, 2026, after the training cutoff, and GS’s on July 14, 2026, inside the training window.

Table S24: Diagnostics of IV-factor persistence, central stock drift, stock volatility, and surface bias. Five-session rows average the scored short-maturity origins and matched contracts; IV changes are in volatility percentage points relative to the observed origin IV. One-session stock rows use the 2025 and August–September 2026 stock-benchmark origins. Surface bias is predicted minus observed IV for the July-cutoff sector surface, in volatility percentage points. LLY reported earnings on August 5, 2026, and GS on July 14, 2026.

Quantity	GS	LLY
<i>Five-session forecasts, short-maturity cohort</i>		
JumpHMM median price change (%)	0.27	0.16
JumpHMM log-return standard deviation (%)	3.98	3.76
Coupled mean IV minus origin IV (points)	0.30	0.18
Coupled mean absolute IV change (points)	2.49	2.47
Direct-surface mean absolute IV change (points)	5.50	4.12
<i>One-session stock return standard deviation (%)</i>		
JumpHMM pilot	1.80	1.70
Realized, 2025	1.97	2.57
EWMA at origin, 2025	1.94	2.52
Realized, August–September 2026	1.40	2.19
EWMA at origin, August–September 2026	2.26	2.14
<i>Held-out July-cutoff surface bias (points)</i>		
August 4	−3.07	−17.90
August 5	−0.96	−0.53
August 6–September 4, mean	1.20	6.17
August 6–September 4, range	−0.68 to 3.59	2.04 to 8.07

G Stock Forecast Evaluation

The stock evaluation separated a check of the existing generator from the comparison of new benchmarks. The saved GS and LLY marginals used daily steps of $1/252$ year and annualized excess log returns. Reconstructing the first-origin forecasts reproduced the saved stock means at both one and five sessions. The original simulator drew the first return state from the stationary distribution, without conditioning on recent returns. In the initialization check, we inferred the current state from available daily returns and advanced it before generating the first future return. The inference tracked both the return state and the number of forced tail-state emissions remaining in a jump episode. Poisson durations retained all but at most 10^{-12} probability, with the remaining mass assigned to the final duration. Missing daily observations advanced the latent distribution without an observation likelihood; an accumulated multi-day return was not treated as a daily observation. The fixed pilot growth shift was removed from observed annualized returns when calculating likelihoods, consistent with the simulated observation model. Table S25 compares this conditional initialization with the original start on the same 2026 endpoints. Both used three 10,000-path replicates, with seeds separate from the subsequent four-method benchmark. The original return-state distributions mixed rapidly under the fitted transitions, so the initial-state adjustment had little effect on five-session central forecasts. The broader exploratory checks, including a fixed 20-return volatility adjustment and Gaussian random walks, are retained in the saved experiment outputs.

Table S25: Stock forecast errors under original and history-conditioned initialization on identical 2026 endpoints. Each ticker has 21 one-session and 17 five-session origins. MAE scores the forecast median; errors are dollars per share and average three 10,000-path replicates. Filtered denotes initialization from available past returns, including inference of remaining jump duration.

Stock	Horizon	Original MAE	Filtered MAE	Original CRPS	Filtered CRPS
GS	1	10.64	10.79	7.99	8.44
GS	5	16.28	16.36	12.99	13.21
LLY	1	19.10	19.08	14.73	14.62
LLY	5	49.58	49.40	35.69	35.35

The benchmark comparison retained the training-fitted JumpHMM parameters with the truncated emission law and tested one adaptive variance rule and one directional model against it. For each annual validation block from 2019 through 2024, regression training responses ended before the validation year and validation endpoints remained within it. The EWMA variance began with the sample variance of the first sixty training daily returns and then updated using only returns observed by each origin. Decay selection minimized $\frac{1}{2}[\log(ha_t) + y_{t,h}^2/(ha_t)]$, where $y_{t,h}$ was the observed cumulative log return over h sessions. We first averaged this loss within each ticker, validation year, and horizon, then gave the resulting groups equal weight. With the selected decay, the regression fitted the next daily return divided by origin volatility. Its four features were the stock’s last daily return, its last five- and twenty-return sums, and SPY’s last five-return sum. Return sums were divided by the corresponding origin volatility and square root of window length; feature columns were further divided by their training root mean square. The ridge objective was mean squared normalized one-session error plus the penalty times the squared coefficient norm. There was no intercept. Penalty selection used $(y_{t,h} - h\hat{\mu}_t)^2/(ha_t)$, with the same group weighting as decay selection. Table S26 gives every candidate’s validation loss. The selected zero-drift limit set all four coefficients to zero for both tickers. Final coefficients and feature scales were fitted using 2014–2024 only and saved before evaluating test forecasts. The two selection losses answer different questions and are not comparable in magnitude.

Table S26: Earlier-data selection of adaptive-volatility and directional-model settings. Losses average ticker, year, and horizon groups equally across 2019–2024 validation blocks. Lower values are better within each selection task. EWMA decay 0.97 and the zero-drift limit were selected; 2025 and 2026 outcomes did not enter these choices.

Selection	Setting	Validation loss
EWMA decay	0.80	-2.921492
EWMA decay	0.90	-3.009741
EWMA decay	0.94	-3.044490
EWMA decay	0.97	-3.065558
EWMA decay	0.99	-3.064379
Ridge penalty	0.01	1.146523
Ridge penalty	0.1	1.143850
Ridge penalty	1	1.138475
Ridge penalty	10	1.136428
Ridge penalty	100	1.136142
Ridge penalty	1000	1.136112
Ridge penalty	Zero drift	1.136109

Historical close series for GS, LLY, and SPY shared the same recorded session grid, with 2,767 closes per ticker in 2014–2024 and 250 in 2025. The 2025 test updated lag features and variance using information through each origin while keeping fitted parameters fixed. The 2026 series began in April after a data gap. Its variance restarted from the 2014–2024 sample estimate and updated through the available April–July daily returns before evaluation. December 2025 and April 2026 were not joined into a daily return. Within 2026, both adjacent exchange-session closes were required to calculate a daily return; missing observations left variance unchanged. Feature windows

used the last required number of valid daily returns, which could span more sessions when observations were missing. The oldest feature input at an evaluated 2026 origin was four calendar days old, whereas the 2025 features had no such gap. Every method used the same observed starting price and endpoint, and none used option quotes. Tables S27 and S28 retain all four candidates and both evaluation periods. The directional and adaptive rows agree exactly because zero drift was selected. Their small median-error differences from the unchanged-price benchmark arise from Monte Carlo estimation of a distribution whose population median equals the origin price. They are not a learned directional effect. Replicate scores, date-level comparisons, input hashes, and settings are retained with the experiment. Overlapping horizons imply dependent observations, and the three simulation seeds measure simulation variation rather than three independent market samples.

Table S27: Complete five-session stock forecast scores for the four selected candidates. Each ticker has 245 origins in 2025 and 17 in August–September 2026. MAE scores medians and RMSE scores means. Monetary quantities are dollars per share; coverage and width describe central 90% intervals. Scores average dates within each of three 10,000-path replicates and then average replicates. Directional equals Adaptive because earlier-data selection chose zero drift.

Year	Stock	Model	Median MAE	Mean RMSE	CRPS	Coverage (%)	Width
2025	GS	JumpHMM	22.31	28.42	16.22	84.4	84.71
2025	GS	Unchanged	22.61	28.75	22.61	–	–
2025	GS	Adaptive	22.62	28.57	16.32	89.8	94.86

2026	LLY	Unchanged	19.01	25.79	19.01	–	–
2026	LLY	Adaptive	18.98	25.78	14.47	76.2	83.93
2026	LLY	Directional	18.98	25.78	14.47	76.2	83.93

H Return Bounds and Sensitivity

All reported JumpHMM price simulations used the conditional emission law in (2). The primary residual cutoff was $b = 10$, with $b = 20$ as the wider sensitivity case. The state locations and scales came from the 2014–2024 fit. We specified the two residual bounds as stress assumptions before rerunning the affected experiments; they were not estimated from the largest observed return or selected to improve forecast errors. We retained the trained parameters and applied truncation only to simulation and the corresponding state-inference likelihoods. Each experiment recomputed its existing pilot or ensemble normalization under the selected cutoff. The Gaussian benchmark distributions retained their original specifications.

Table S29 translates the state-specific bounds to daily percentage returns using the chronological experiment’s independent pilot growth shift. These are support limits over all fitted states, not central forecast intervals. The probability removed refers to the original standardized Student- t distribution. It does not represent the probability of all large stock moves, since different state locations and scales also contribute to return variation. Normalization constants differ slightly between experiments, so their shifted daily support limits can differ.

Table S29: Emission bounds under the primary and wider residual cutoffs. Daily return limits include the chronological pilot growth shift and the 1/252 year step. Removed mass is the probability excluded from the original Student- t emission, in percent.

Stock	b	Lower return (%)	Upper return (%)	Removed mass (%)
GS	10	-26.47	38.99	0.0171
GS	20	-42.73	81.83	0.0006
LLY	10	-21.23	38.98	0.0171
LLY	20	-38.22	82.11	0.0006

The sensitivity comparison reran the fitted illustrations, paired IV ablation, both chronological option cohorts, and stock benchmarks with the same seeds and inputs at each cutoff. Table S30 reports call-loss summaries for the fitted illustrations and the ten-transition coupled-factor ablation. Table S31 reports the shorter-maturity five-session coupled option errors and the JumpHMM stock distribution scores. Differences reflect the changed emission law and recomputed normalization constants, with the other fitted components held fixed.

Table S30: Short-call P&L sensitivity to the residual cutoff, in dollars per share. The fitted illustration uses 1,000 paths and terminal P&L; the coupled-factor ablation uses 3,000 paths and liquidation after ten trading transitions. Expected shortfall averages outcomes at or below the 5% quantile.

Experiment	Stock	b	Mean P&L	5% quantile	ES _{5%}
Ten-session ablation	GS	10	0.194	-35.194	-69.817
Ten-session ablation	GS	20	0.191	-35.203	-69.828
Ten-session ablation	LLY	10	6.260	-20.279	-45.182
Ten-session ablation	LLY	20	6.263	-20.273	-45.174
Terminal illustration	GS	10	-2.194	-86.183	-130.770
Terminal illustration	GS	20	-2.213	-86.243	-130.833
Terminal illustration	LLY	10	10.605	-51.956	-94.176
Terminal illustration	LLY	20	10.595	-52.006	-94.228

Table S31: Five-session forecast sensitivity to the residual cutoff. Option MAE scores the coupled-factor forecast mean in the shorter-maturity cohort. Stock CRPS scores the JumpHMM forecast distribution in each period. Values are dollars per share and retain the date and replicate weighting of the main comparisons.

Quantity	Stock	$b = 10$	$b = 20$	Change
Option MAE, 2026	GS	4.193743	4.200236	+0.006492
Option MAE, 2026	LLY	11.587739	11.587747	+0.000008
Stock CRPS, 2025	GS	16.221054	16.221403	+0.000349
Stock CRPS, 2025	LLY	29.604370	29.603983	-0.000386
Stock CRPS, 2026	GS	13.025558	13.025238	-0.000320
Stock CRPS, 2026	LLY	35.602434	35.601074	-0.001360

The finite support makes stock-price moments and short-call expected losses finite at every fixed horizon. This is a mathematical property of the specified model, not evidence that its support limits are correct. Agreement across these two cutoffs assesses the reported finite simulations; it does not establish insensitivity to arbitrary return-tail specifications or accuracy in unobserved market extremes.
