Abstract

Simulating American-option values requires a volatility input at every date along a stock path. In this study, we developed a framework that supplied this input while allowing the stock-return model to be chosen separately. Fitted neural surfaces set targets for contract-specific implied-volatility (IV) factors along JumpHMM stock paths, and an American lattice converts each state into option values and price sensitivities. Sector-specific surfaces reduced in-sample IV root mean squared error from 12.48 to 10.24 volatility percentage points on 234,549 observations from 31 tickers. A paired ablation showed that IV dynamics changed interim marks on identical stock paths while preserving terminal payoffs. Temporal evaluation included 53 surface folds and a July-cutoff fit tested against August–September 2026 observations. Five-session option forecasts used 17 origins per ticker. Mean-forecast absolute errors under the coupled factor were \$4.20 for Goldman Sachs and \$11.59 for Eli Lilly, compared with \$4.22 and \$11.62 under frozen IV. Supplying subsequently observed stock paths reduced option errors in a diagnostic that used future information. Separate stock tests covered 245 five-session origins per ticker in 2025 and 17 in 2026. Central forecasts remained close to an unchanged-price benchmark. Adaptive volatility improved Eli Lilly’s distribution scores in both periods but not Goldman Sachs’s, and earlier validation selected zero drift for a simple directional model. The framework supports controlled comparisons of IV assumptions; these tests did not establish a consistent forecasting advantage. Incomplete contract histories, dependent forecast dates, and residual strike inconsistencies limited broader conclusions.

1 Introduction

Evaluating an option strategy requires a model of how contract values change as market conditions evolve. A position that appears profitable at expiration may incur substantial losses before that date, when a trader may need to close or hedge it. Stress tests and trading-system studies therefore require paths of option values and risk sensitivities as well as paths of the underlying stock price. This requirement is particularly important for American options because their values also reflect the opportunity to exercise before expiration. Historical option quotes provide observations of these quantities over realized market conditions, but a simulation must supply them for stock paths that have not occurred. Implied volatility (IV) provides a useful connection between market quotes and an option-pricing model because it is the volatility input recovered by inverting an observed price [Black and Scholes \[1973\]](#). To use this connection in a synthetic market, the simulator needs a rule for assigning IV across strikes and maturities and updating those values as the stock path unfolds. The stock model must also represent the return behavior relevant to the intended experiment,

*Corresponding author.

including features such as heavy tails and volatility clustering [Cont \[2001\]](#). The resulting modeling problem is to produce complete option-contract paths whose response to these stock scenarios can be examined and interpreted.

Existing approaches address different parts of this problem through their choices of return dynamics, volatility representation, and pricing model. Parametric models such as stochastic alpha beta rho (SABR) and stochastic volatility inspired (SVI) provide compact descriptions of volatility smiles [Hagan et al. \[2002\]](#), [Gatheral \[2004\]](#). Neural methods allow more flexible representations and can accelerate pricing and calibration within specified volatility models [Horvath et al. \[2021\]](#), [Bayer and Stemper \[2018\]](#). Models of IV-surface dynamics describe changes in level, skew, and curvature through common factors [Cont and da Fonseca \[2002\]](#), with more recent methods incorporating static arbitrage constraints into surface simulation [Cont and Vuletić \[2023\]](#). Local- and stochastic-volatility models instead place stock and volatility dynamics within a joint pricing model [Dupire \[1994\]](#), [Derman and Kani \[1994\]](#), [Heston \[1993\]](#). These approaches already support generation beyond the observed quotes. A different design question arises when the researcher wants to retain a physical stock-return model chosen for its empirical behavior and vary the volatility assumptions separately. Historical and generative return models can reproduce important features of equity data [Cont \[2001\]](#), [Wiese et al. \[2020\]](#), but their stock paths alone do not specify an option-implied volatility surface. For example, the Jump Hidden Markov Model (JumpHMM) generates returns through Markov transitions among return states and explicit visits to tail states [Alswaidan and Varner \[2026\]](#). Those returns determine terminal option payoffs while leaving the IV input for interim valuation unspecified. An evolving contract-level IV model can supply that input to a recombining American lattice [Cox et al. \[1979\]](#), [Leisen and Reimer \[1996\]](#). This separation allows researchers to compare volatility assumptions on the same stock paths, provided that the accuracy and consistency of the resulting option prices are evaluated explicitly.

In this study, we developed a computational framework that connected JumpHMM stock paths to fitted IV surfaces, contract-specific square-root factors, and American-option valuation. We fitted the surfaces to observed option data before simulation and used them to set variance targets as moneyness and remaining time to expiration changed. Each contract’s variance factor evolved around its target and supplied the volatility input for a lattice calculation of option value and price sensitivities. This construction allowed the IV dynamics to change without replacing the physical return generator or using future option quotes during simulation. We evaluated the surface representation on 234,549 observations from 31 tickers and fifteen snapshots, comparing global, sector-specific, and per-ticker parameter sharing. Temporal holdouts examined transfer to withheld dates and the contribution of earnings-calendar inputs. We then simulated Goldman Sachs (GS) and Eli Lilly (LLY) contracts and conducted a paired ablation that held stock paths fixed across five IV variants. This experiment measured how the IV assumptions affected interim marks and early-liquidation profit and loss (P&L), with identical terminal payoffs providing a control for interpretation. Lattice refinement and strike checks assessed whether the measured differences reflected numerical error or inconsistencies across contracts. We extended the surface evaluation across 53 chronological folds and fitted a separate July-cutoff model for comparison with later GS and LLY option observations. These tests distinguished conditional surface transfer, joint stock–option forecasting, and a diagnostic supplied with the subsequently observed stock path. To examine the stock contribution separately, we compared the retained JumpHMM with unchanged-price, adaptive-volatility, and simple directional benchmarks in 2025 and August–September 2026, selecting the new models’ settings using earlier data. This evaluation tested the accuracy of the stock inputs without changing the original IV ablation. The resulting evidence addressed the framework’s use for controlled comparisons and the limits of its forecasting performance, while joint no-arbitrage consistency remained a separate requirement.

2 Methods

2.1 Pipeline and stock-path generation

The framework connected stock-path generation to contract-specific IV dynamics and American-option valuation. Information passed through the three stages in this order:

$$\text{JumpHMM stock path} \longrightarrow \text{contract IV factor} \longrightarrow \text{American lattice price and Greeks.} \quad (1)$$

Market option data entered during the offline surface fit. Each simulated step then used that fitted surface without requiring a new option quote or feeding lattice prices back into the fit. Stock paths came from pretrained single-ticker JumpHMM marginals fitted to equity histories from 2014–2024 [Alswaidan and Varner \[2026\]](#). The model represents excess growth rates with latent states and location-scale Student- t emissions. A jump mechanism increases visits to tail states to reproduce features such as heavy tails and volatility clustering [Cont \[2001\]](#). The pretrained artifact contained 424 ticker marginals with 50 states and 2,767 training days. Its growth rates used a 1/252 year step and zero risk-free offset. A Student- t copula can couple these marginals across assets [Demarta and McNeil \[2005\]](#), although the reported scenarios used one ticker at a time.

2.2 Offline IV-surface calibration

We collected option-chain data from Alpaca Markets using a free-tier account. The frozen corpus contained 457 ticker files in fifteen snapshot directories and 234,549 observations after filtering. Calls and puts required a positive bid and positive calendar days to expiration (DTE). We also required reported IV strictly between 0.01 and 2.0 and strike/spot between 0.8 and 1.2 inclusive. Spot was the stored underlying-session close. Both option types entered the same loss, and repeated contracts across snapshots remained separate observations. The calibration target was Alpaca’s reported IV field. Alpaca documents a Black–Scholes calculation with an iterative solver based on price sensitivity to volatility (Vega) [Alpaca Markets \[2026\]](#). Snapshot labels and underlying-session dates defined the respective temporal splits as detailed in Supplementary Table S1. This corpus provided extensive cross-sectional coverage over a short observation window for comparing a five-parameter log-polynomial with neural surfaces shared globally, within sectors, or fitted separately to individual tickers. Parametric models such as SABR and SVI motivate compact representations of IV smiles [Hagan et al. \[2002\]](#), [Gatheral \[2004\]](#). Neural representations allow more flexible shapes [Horvath et al. \[2021\]](#), [Bayer and Stemper \[2018\]](#). We exponentiated each shape function to keep its output positive. Neither calendar monotonicity nor strike convexity was imposed during fitting. The resulting fitted surfaces therefore required separate no-arbitrage checks. We used the following parametric shape for ticker i , calendar days to expiration τ , and moneyness $m = K/S$:

$$\psi_\beta(\tau, m) = \exp[\beta_1 \ln \tau + \beta_2 \ln m + \beta_3 \ln \tau \ln m + \beta_4 (\ln m)^2 + \beta_5 (\ln \tau)^2]. \quad (2)$$

The corresponding IV prediction was defined by a ticker level and the surface shape:

$$\hat{\sigma}_i^2(\tau, m) = \theta_i \psi(\tau, m), \quad \theta_i > 0, \quad \psi(\tau, m) > 0. \quad (3)$$

The fitted squared IV also defined the variance target on each observation date:

$$\theta_{\text{cal}}(i, \tau, m) = \theta_i \psi(\tau, m). \quad (4)$$

The neural network (NN) models replaced the log-polynomial with a positive network output. We defined the two-input neural surface with the expression:

$$\psi_{\text{NN}}(\tau, m; w) = \exp[\text{NN}(\text{std}(\ln \tau), \text{std}(\ln m); w)]. \quad (5)$$

Per-ticker fits required at least 2,000 observations; other tickers retained sector fits. Inputs were standardized using the training rows. Networks with at least 5,000 per-ticker observations, or 2,000 pooled group observations, used a $2 \rightarrow 16 \rightarrow 16 \rightarrow 1$ architecture with tanh activations and 337 parameters. Smaller qualified groups used $2 \rightarrow 8 \rightarrow 8 \rightarrow 1$ with 105 parameters. For the earnings analysis, we appended two standardized inputs: signed days to the ticker’s nearest earnings date, clipped to $[-30, 30]$, and the minimum absolute earnings distance among same-sector peers, clipped to 30. The resulting $4 \rightarrow 16 \rightarrow 16 \rightarrow 1$ network had 369 parameters. Earnings dates came from the public Yahoo Finance calendar. These event features entered only the temporal calibration comparison and remained inactive in the GS and LLY scenario drivers. To fit each network representation, we optimized its weights and ticker log levels jointly by minimizing the average squared difference between predicted and reported IV. Lower loss indicated closer agreement with the observed values. This criterion assigned equal weight to every retained observation. We minimized the following training objective:

$$\min_{w, \{\ln \theta_i\}} \frac{1}{n} \sum_{j=1}^n \left[\sqrt{\theta_{i(j)} \psi_{\text{NN}}(\tau_j, m_j; w)} - \sigma_{\text{market}, j} \right]^2. \quad (6)$$

The log levels were initialized from each ticker’s mean squared market IV. Adam training used a decreasing learning-rate schedule, at most 2,000 epochs, and a best-training-loss checkpoint with patience 200. Because a constant can be shifted between $\ln \theta_i$ and the output bias of the network, these two components are not separately identified. Only their product in (3) is interpretable without an additional normalization constraint.

2.3 Contract-specific dynamic IV factors

The standard Heston model couples an asset-price diffusion to a square-root instantaneous-variance process Heston [1993]. Its variance follows the stochastic differential equation:

$$dv_t = \kappa(\theta - v_t)dt + \sigma_v \sqrt{v_t} dW_t^v. \quad (7)$$

Here κ is the mean-reversion rate, θ is long-run variance, and σ_v is volatility of variance. The standard Heston model correlates the variance Brownian motion with the Brownian motion driving the stock. We used the square-root process to evolve a separate implied-variance state for each contract along a stock path supplied by JumpHMM. Each state reverted toward a target from the fitted surface and supplied the volatility input for that contract’s lattice price. The lattice treated this input as constant within each pricing calculation even though it changed between simulated dates. This construction gave the square-root process the role of a dynamic IV factor. It did not represent the underlying asset’s instantaneous return variance in a standard Heston economy. Within this construction, each scenario contract $a = (i, K, T)$ received a variance state $v_{a,t}$ with a target that changed as spot and remaining calendar DTE changed. Evaluating the fitted surface at the current contract state gave the target:

$$\bar{v}_{a,t} = \theta_i \psi_{\text{NN}}(\tau_t, K/S_t). \quad (8)$$

The factor started exactly on the fitted entry surface:

$$v_{a,0} = \bar{v}_{a,0}. \quad (9)$$

At each later date, the lattice IV was the square root of that contract’s factor:

$$\sigma_{a,t} = \sqrt{v_{a,t}}. \quad (10)$$

The put and call on a stock shared its path and the variance shock but retained their own variance states and surface targets. The stock and factor updates advanced only on exchange sessions. For the original fitted illustrations, we shifted every simulated growth-rate observation by a constant so that the ensemble mean matched a prespecified annual growth prior. We then standardized the one-session log returns across all paths and dates. The ablation used independent pilot estimates for these constants as described in Section 2.5. We defined the standardized return shock entering the IV update with the expression:

$$Z_{j,t}^S = \frac{\Delta \ln S_{j,t} - \overline{\Delta \ln S}}{s_{\Delta \ln S}}. \quad (11)$$

An independent standard normal shock supplied the remaining variation. Combining the return and independent shocks gave the factor shock:

$$Z_{j,t}^v = \rho Z_{j,t}^S + \sqrt{1 - \rho^2} Z_{j,t}^\perp, \quad Z_{j,t}^\perp \sim \mathcal{N}(0, 1). \quad (12)$$

The coefficient ρ was fixed at -0.6 . It was a return-shock coupling parameter, not a calibrated correlation between two Brownian motions in a standard Heston model. We advanced each factor with a hard-floor Euler update and trading-year step $\Delta t = 1/252$:

$$v_{a,t+1} = \max \left\{ v_{a,t} + \kappa(\bar{v}_{a,t} - v_{a,t})\Delta t + \sigma_v \sqrt{\max(v_{a,t}, 0)} \sqrt{\Delta t} Z_{j,t}^v, v_{\min} \right\}. \quad (13)$$

We fixed $\kappa = 15$, $\sigma_v = 0.5$, and $v_{\min} = (0.005)^2$ as scenario assumptions. The floor protected the numerical pricer when the parameters did not satisfy the Feller condition Andersen [2008]. The repository also contains a proposed state-dependent level and aggregate tail-state mood multiplier. Both terms remained inactive in every reported experiment. The fitted surface therefore determined the target throughout the study, and the fixed coefficient ρ determined return-shock coupling. Evaluating the additional mechanisms would require state-conditioned option histories.

2.4 American-option pricing, calendar clock, and terminal profit and loss

Recombining lattices price American options by comparing continuation with immediate exercise at every node during backward induction [Broadie and Detemple \[1996\]](#). The Cox–Ross–Rubinstein (CRR) construction sets its up and down factors from the supplied volatility [Cox et al. \[1979\]](#). Alternatives include the moment matches of Jarrow–Rudd and Tian [Jarrow and Rudd \[1982\]](#), [Tian \[1993\]](#) and the Peizer–Pratt inversion used by Leisen–Reimer to improve finite-step convergence [Leisen and Reimer \[1996\]](#). Both pricers used here accepted one IV value for a given contract and date. The GS and LLY contracts ran from April 28 to May 29, 2026. This interval contained 31 calendar days and 22 exchange-session transitions after excluding weekends and the May 25 market holiday. The surface and lattice used calendar DTE, with $\tau_t/365$ years entering the pricer. The stock and variance states advanced on the 22 trading transitions. Within this common clock, corpus-wide dollar-price checks used a 200-step CRR American tree. Scenario marks and Greeks used a 201-step Leisen–Reimer (LR) American tree. Both stages used a constant risk-free rate of 4.25% and continuous dividend yield $q = 0$. At expiration, the model replaced the lattice value with intrinsic value.

We calculated terminal profit and loss for a short position that received market mid p_0 as follows:

$$\Pi_T^{\text{put}} = p_0^{\text{put}} - \max(K - S_T, 0), \quad \Pi_T^{\text{call}} = p_0^{\text{call}} - \max(S_T - K, 0). \quad (14)$$

Equation (14) shows that terminal profit and loss depended on the JumpHMM terminal stock price, strike, and premium. Dynamic IV affected interim option marks and Greeks, but not a held-to-expiration payoff. All option premiums, values, and P&L are dollars per underlying share; monetary amounts for a standard 100-share contract are 100 times these values. Premium financing was omitted. For low-volatility states or saturated Leisen–Reimer probabilities, an American CRR tree supplied the mark, retaining the immediate-exercise comparison. We calculated price sensitivities, or Greeks, by central finite differences on the same Leisen–Reimer pricer. Delta measured price sensitivity to spot, and gamma measured the change in delta with spot. Spot bumps were $\pm 1.5\%$ of spot for delta and gamma. Volatility bumps were ± 0.005 , and Vega was reported per one volatility percentage point. We assumed execution at the observed mid, no transaction costs, no margin constraint, no early assignment before the plotted horizon, and no discrete dividends.

2.5 Paired dynamic IV ablation

We tested which IV components changed interim valuation by holding the stock paths, contracts, entry premiums, and pricing assumptions fixed across five variants. Frozen IV retained each contract’s fitted entry value of v . The direct surface set $v_{a,t} = \bar{v}_{a,t}$ at every date. Deterministic mean reversion used (13) with $\sigma_v = 0$. An uncoupled stochastic factor used $\sigma_v = 0.5$ and $\rho = 0$, and the full factor used $\sigma_v = 0.5$ and $\rho = -0.6$. The last three variants retained $\kappa = 15$. All variants started at the same fitted entry IV and reused the same independent normal innovation wherever a stochastic factor was active. The evaluation applied this paired design to three seeds per ticker, 20260429, 20260430, and 20260431, with 1,000 paths per seed. For this ablation, a separate 10,000-path pilot with seed 20260905 supplied a constant growth shift to the 10% annual prior and the resulting one-session log-return mean and standard deviation. Those constants were frozen before generating evaluation paths. Unlike the original fitted illustrations, evaluation paths were therefore not recentered or standardized using their own future realizations. The pilot and evaluation simulations each used 22 transitions, and every return was applied once after the initial stock price.

The primary endpoint was liquidation after ten trading transitions, on May 12, with 17 calendar days remaining. Secondary endpoints used five, fifteen, and twenty transitions. The short-position liquidation P&L and its paired difference from the direct-surface reference were given by the following expressions:

$$\Pi_{a,t}^{(b,j)} = p_{a,0} - P_{a,t}^{(b,j)}, \quad D_{a,t}^{(b,j)} = \Pi_{a,t}^{(b,j)} - \Pi_{a,t}^{(\text{surface},j)}. \quad (15)$$

Here b denotes the IV variant and j the shared stock path. We reported mean P&L, its standard deviation, the 5% quantile, and 5% expected shortfall, defined as mean P&L at or below that quantile. The paired mean difference had Monte Carlo standard error $s_D/\sqrt{n}$, with smaller values indicating more precise simulation estimates of that mean. Mean absolute mark differences measured the size of pathwise changes even when positive and negative differences canceled in the mean. We reported each seed separately and pooled 3,000 paths per ticker. These uncertainty estimates condition on the fitted models and pilot constants. We also checked exact agreement of entry marks and terminal

payoffs across variants and examined the numerical accuracy and strike consistency of the intervening prices. Numerical checks compared 201- and 401-step marks on the first twenty paths of every evaluation seed at transitions ten and twenty. A separate audit used eleven fixed strikes from 0.8 to 1.2 times entry spot, the first fifty paths of the first seed, and transitions zero, ten, and twenty. Calls and puts at the scenario expiry shared the same shocks. We checked intrinsic and upper price bounds, strike monotonicity, vertical-spread bounds, and convexity at both tree depths, counting violations larger than \$0.01 per share. Convexity violations were measured as the dollar excess above the neighboring linear interpolation. Entry was counted once per variant and option type. These are necessary strike conditions; the audit did not test calendar or dynamic no-arbitrage.

2.6 Chronological surface and forecast evaluation

We extended the temporal evaluation in two stages to distinguish surface transfer from forecasting complete contract paths. The first stage used the completed expanding-window sector-network experiment on 58 capture dates through July 17, 2026. For each of 53 folds, the network fitted the first k dates and predicted the next captured date, with $k = 5, \dots, 57$. This experiment retained the original filters and capture-date labels, used two surface inputs, and calculated feature standardization from each training fold alone. Its 986,492 accepted observations contained no crossed or missing asks and no missing or nonpositive displayed bid or ask sizes under an independent reconstruction of the saved row counts. Since prediction used the later observation’s stock price to calculate money-ness, the experiment measured conditional transfer of the surface across dates. It did not evaluate stock forecasts or the stochastic IV factor. The second stage fitted six sector networks once using 1,173,538 observations from 68 underlying sessions ending July 31. Their architectures and training schedule matched the existing two-input sector model, with seed 42 and a maximum of 2,000 epochs. Training-loss checkpoints, ticker levels, and training-only standardization were saved with the fitted models. The later sample contained 425,061 filtered IV observations across 23 sessions from August 4 through September 4. These observations supplied the final evaluation and did not select architectures, fitting windows, parameters, or seeds.

The second stage used an explicit capture audit before fitting or selecting contracts. The collector recorded retrieval times in UTC and stored the underlying-session close with each option row. We accepted retrievals after 20:00 UTC on that session and before 13:30 UTC on the next exchange session. This rule admitted overnight retrievals of a previous close while excluding twenty intraday repeat captures. We retained the latest eligible file per ticker and underlying session and one row per exact option symbol. Two-sided quotes required finite positive bids, noncrossed asks, and positive displayed sizes. Surface fitting additionally required the original IV and money-ness ranges and positive DTE, recomputed from expiration and the underlying session. Only files retrieved by the end of July 31 could enter training. Retrieval times were not exchange quote timestamps, so this audit did not establish quote freshness or exact stock–option synchronization. This limitation applied to the interpretation of both IV and dollar-price errors.

The forward test used GS and LLY at successive observed origins in August and early September, with planned horizons of one and five exchange sessions. Each origin supplied one put and one call with 25–45 calendar DTE. For each option type, we selected the expiration nearest 31 DTE and then the strike nearest $K/S = 0.95$ for puts or 1.05 for calls, breaking ties by earlier expiration and symbol. Selection used only the origin observations. We matched each selected symbol at its exact endpoint session and recorded missing endpoints without substituting another contract or capture date. The collection’s rolling maturity buckets left none of these roughly monthly contracts observed five sessions later. We retained their one-session evaluation and added a separate shorter-maturity cohort with 10–21 DTE, choosing the expiration nearest 14 DTE with the same strike and tie rules. This availability-driven amendment preceded inspection of aggregate forecast errors and was recorded in the experiment protocol. The shorter cohort supplied the five-session case study; it did not replace the original contracts or validate their longer trajectories. All five IV variants began at the contract’s observed origin IV. To compare their evolution without confounding the result with the fitted surface’s initial level error, we rescaled the frozen variance target once at the origin:

$$\bar{v}_{a,t}^* = \sigma_{a,0,\text{obs}}^2 \frac{\bar{v}_a(S_t, \tau_t)}{\bar{v}_a(S_0, \tau_0)}. \quad (16)$$

This anchoring defined a separate forecast experiment; the original sensitivity ablation retained its fitted initialization. Frozen IV held the common origin value, direct evaluation followed $\bar{v}_{a,t}^*$, and

the three evolving factors used that anchored target with the previously specified parameters. Each origin used 1,000 JumpHMM paths and shared normal innovations across IV variants. The initial return state was drawn from the saved model’s stationary distribution; recent returns did not update that state in the original forecast. An independent 10,000-path pilot per ticker supplied the growth shift to the existing 10% annual prior and the one-session return normalization. Evaluation paths were not recentered. A zero-log-drift Gaussian random walk with the pilot return standard deviation provided a stock benchmark. Origin stock prices and IV updated as observations became available, but fitted parameters remained fixed. This was a retrospective evaluation at successive forecast origins, rather than a single forecast issued on July 31.

We scored forecast mean option values against the later bid–ask midpoints, using mean absolute error as the prespecified primary point metric. We retained that calculation and added median-based absolute errors to distinguish the choice of point summary from the IV comparison. Signed error, root mean squared error, and the fraction of predicted means inside the quoted spread supplied complementary price diagnostics. Distributional evaluation used the empirical continuous ranked probability score (CRPS) [Gneiting and Raftery \[2007\]](#), which rewards concentration near the observed value while penalizing misplaced probability mass. For N simulated values P_j and observed midpoint y , we calculated the score as:

$$\text{CRPS} = \frac{1}{N} \sum_{j=1}^N |P_j - y| - \frac{1}{2N^2} \sum_{j=1}^N \sum_{k=1}^N |P_j - P_k|. \quad (17)$$

Smaller values indicate better distributional forecasts. We also reported central 90% interval coverage and width. Scores were averaged across matched contracts within each ticker and origin before averaging dates, and stock forecast scores were reported separately. A diagnostic repeated IV evolution using the observed stock path only when every intervening session was available. It was explicitly conditional on realized stock information and therefore did not constitute a joint forecast. Repricing with the endpoint’s reported IV in the same lattice supplied a further diagnostic of pricing discrepancies. All monetary scores were dollars per share. Overlapping horizons and common market movements made forecast dates and contracts dependent, so simulated path counts were not treated as independent market observations. The illustrative forecast was the earliest GS origin in the shorter-maturity cohort with both selected contracts observed at the five-session endpoint, regardless of its forecast errors.

2.7 Stock forecast benchmarks

The option forecast errors motivated a separate evaluation of the stock generator. We first checked return scaling and price reconstruction and repeated the 2026 stock forecasts after conditioning the initial state on the available return history. This diagnostic retained the fitted parameters and tracked the remaining duration of a jump episode during state inference. We then compared four stock forecast methods: the saved 2014–2024 JumpHMM, an unchanged-price benchmark, a Gaussian model with adaptive volatility, and the same volatility model with a simple directional regression. The original JumpHMM retained its stationary initialization and independent-pilot growth shift. The adaptive model updated daily variance with an exponentially weighted moving average (EWMA) of squared log returns. The regression estimated a daily drift from the stock’s most recent one, five, and twenty valid daily returns and SPY’s most recent five valid daily returns. Cumulative-return features were normalized by origin volatility and the square root of their window length. A ridge penalty shrank the coefficients toward zero, and the regression had no intercept. Let $u_t = \log(S_t/S_{t-1})$ denote an observed daily return and a_t its estimated daily variance at the forecast origin. The adaptive and directional models used the equations:

$$a_t = \lambda a_{t-1} + (1 - \lambda) u_t^2, \quad \log \frac{S_{t+h}}{S_t} = h\mu_t + \sqrt{a_t} \sum_{j=1}^h Z_j, \quad Z_j \sim \mathcal{N}(0, 1). \quad (18)$$

The adaptive model set $\mu_t = 0$, while the directional model used the regression estimate. Drift and variance remained fixed within each forecast horizon, so neither model received future stock or market returns. The unchanged-price benchmark supplied only a point forecast. It was not assigned an uncertainty interval for comparison with the stochastic models. These stock tests did not replace the paths used in the original option evaluation or the paired IV ablation.

We selected the new models’ settings using expanding annual validation blocks from 2019 through 2024, with earlier observations used for each regression fit and feature scale. One EWMA decay and one ridge penalty were chosen across both tickers by weighting each ticker, validation year, and horizon equally. Candidate decays were 0.80, 0.90, 0.94, 0.97, and 0.99. Ridge penalties ranged from 0.01 to 1000 and included the zero-drift limit. Decay selection minimized Gaussian log loss for cumulative log returns, while penalty selection minimized squared cumulative-return error divided by forecast variance. After selection, we fitted the regression using 2014–2024 observations and froze its coefficients and scaling. The additional 2025 stock dataset supplied 249 one-session and 245 five-session origins per ticker. The August–September 2026 test retained the original 21 one-session and 17 five-session stock outcomes per ticker. All methods used identical starting prices and endpoints. Origin features and variance updated only with observations then available; missing closes were not filled or converted into multi-session returns treated as one-day observations. Each stochastic model used 10,000 paths per origin and three fixed simulation seeds, with shared Gaussian innovations between the adaptive and directional candidates. We reported median-based MAE, mean-based RMSE, CRPS, and central 90% interval coverage and width. Medians minimize expected absolute loss, while means minimize expected squared loss [Hyndman and Athanasopoulos \[2021\]](#). Scores were averaged across dates within each simulation replicate and then across replicates. The model classes were proposed after inspecting the original 2026 misses, but neither the 2025 nor 2026 outcomes selected their settings. We therefore reported both periods separately and treated the 2026 follow-up as exploratory.

3 Results

We first examined whether greater surface flexibility and narrower parameter sharing improved the fit to observed IV. The filtered corpus contained 234,549 observations from 31 tickers across fifteen snapshots and six market groups (Supplementary Tables [S2](#) and [S1](#)). We fitted global parametric, global neural, and sector-specific neural shapes using the same loss and retaining ticker-specific levels in every model. Root mean squared error (RMSE) measured agreement with reported IV in volatility percentage points, with lower values indicating a closer fit. Replacing the global parametric shape with a global neural surface reduced pooled in-sample error from 12.48 to 11.47 points, and sector-specific networks reduced it further to 10.24 points (Table 1). The sector gains extended across all six groups and were largest in exchange-traded funds (ETFs) and financials (Supplementary Table [S3](#)). Technology and healthcare nevertheless retained the largest errors and contained the weakest individual ticker fits (Supplementary Table [S7](#)). These remaining differences motivated separate surfaces for tickers with sufficient observations. Assigning per-ticker networks where the sample threshold was met reduced pooled error to 9.73 points while retaining sector fits for the remaining tickers (Table 1). Most qualified tickers improved under this change (Supplementary Table [S4](#)). The smile panels nevertheless showed that lower pooled error did not ensure agreement on an individual date (Fig. 1). Their observations came from May 11, while all three displayed surfaces had been fitted across fifteen snapshots. Near the money, the per-ticker fits exceeded observed IV by an average of 9.45 percentage points for MSFT and 7.90 points for LLY. The corresponding biases were small for SPY and GS, while AVGO was underpredicted by 5.37 points (Supplementary Table [S5](#)). These discrepancies were present in predictions at the observed contracts. A surface with moneyness and maturity as its only inputs could not adjust its level independently for May 11. Thus, greater flexibility and narrower sharing improved the pooled fit but left substantial date-specific errors. The interpretation rested on predicted IV because the ticker level and neural output bias were not separately identified in (3). Lower error on the calibration observations alone did not establish more accurate option prices or better performance on future dates.

Table 1: In-sample IV RMSE on 234,549 observations, reported in volatility percentage points. Each model fitted one ticker level jointly with its shape parameters. The final row used per-ticker neural surfaces for the 29 qualified tickers and sector surfaces for PFE and BMJ.

Model	RMSE	Reduction from parametric
Parametric shape, global	12.48	reference
Neural shape, global	11.47	8.1%
Neural shape, six sectors	10.24	17.9%
Neural shape, per-ticker with fallback	9.73	22.0%

Figure 1: In-sample comparison of the implied volatility (IV) observed on May 11, 2026 with surfaces fitted across all fifteen calibration snapshots. Panels show (a) SPY, (b) NVDA, (c) MSFT, (d) LLY, (e) GS, and (f) AVGO, with 7, 7, 9, 11, 11, and 9 calendar days to expiry, respectively. Circles and diamonds distinguish reported call and put IV; solid, dashed, and dotted curves show per-ticker neural, sector neural, and global parametric fits. The legend applies to all panels. The MSFT and LLY fits overpredict IV near the money; Supplementary Table S5 reports the corresponding errors.

To examine the pricing consequences of the fitted surfaces, we passed their IV predictions to the American lattice and compared the resulting values with observed option mids. The May 11 capture provided contracts for which dollar errors could also be judged against the local bid-ask half-spread. This comparison was needed because the same IV error can have different pricing consequences across contracts, and an improvement in pooled IV fit need not place a model price within the quoted spread. Only about one third of fitted SPY, NVDA, and LLY prices fell within the half-spread around the mid, compared with 88% for GS (Fig. 2; Supplementary Table S6). The largest median absolute error occurred in LLY at \$4.01 per share. To distinguish the contribution of the fitted IV input from the rest of the pricing calculation, we repeated the calculation with each contract's reported market IV in the same lattice. This substitution reduced the LLY median error to \$0.67 per share

and pointed to a substantial contribution from the surface’s date-specific IV level. The remaining errors also showed that the reported IV did not reproduce every captured mid under the American pricer. Since May 11 entered the full-corpus fits, these results described the pricing consequences of calibration error on an observed date. They established a reason to assess dollar-price accuracy alongside IV fit when evaluating the surface representation.

Figure 2: In-sample comparison of CRR American-option prices with market mids across moneyness for SPY, NVDA, LLY, and GS on May 11, 2026. Errors are lattice price minus market mid. Curves show the parametric, sector, per-ticker, and market-IV reference inputs. The gray ribbon is the median local bid-ask half-spread by moneyness bin. A point inside the ribbon has an absolute pricing error below that local half-spread.

We next examined whether the fitted surfaces transferred to withheld dates and whether earnings-calendar information improved that transfer. Removing May 11 and retraining the sector models on the other fourteen dates gave pooled error of 10.21 volatility percentage points on the training observations and 10.89 points on the holdout (Supplementary Table S8). Energy and retail had the largest increases in error, so the modest pooled gap concealed differences among sectors. A separate temporal split then tested whether calendar inputs supplied information beyond moneyness and maturity. Configuration A used those two inputs alone, while Configuration C added distances to ticker and peer earnings dates on exactly the same training and test rows. The added inputs reduced error on the two-day holdout from 13.03 to 11.98 volatility percentage points (Table 2). Several technology tickers with nearby peer reports improved, although the gains did not extend to every ticker (Supplementary Table S9). This comparison supported the usefulness of calendar information within the tested split. Configuration B examined the effect of removing observations near earnings before fitting the two-input model. Its similar training and test errors applied to the retained subset after most observations had been discarded. Because that filtering changed the composition of both samples, it could not attribute the original error gap to earnings alone. Every test ticker appeared in training, and neither temporal experiment covered repeated dates and training seeds. The results therefore supported limited transfer within the available window and a benefit from earnings inputs on one fixed holdout. They did not establish that the surfaces would retain the same accuracy across other market periods.

Table 2: Temporal-holdout comparison. Training used six snapshots labeled April 14 through April 22, 2026, and testing used April 23–24; every test ticker appeared in training. Errors and gaps are in volatility percentage points. Configuration B used different row sets from A and C.

Configuration	N_{tr}	N_{te}	Train RMSE	Test RMSE	Gap
A: pooled, two inputs	103,897	26,833	8.05	13.03	+4.99
B: non-earnings, two inputs	29,383	4,516	8.02	7.96	−0.06
C: earnings-aware, four inputs	103,897	26,833	7.61	11.98	+4.36

Having evaluated the fitted surfaces, we used them to generate complete contract paths and examine how the stock and IV inputs entered American-option valuation. We selected one put and one call for each of GS and LLY from the April 28 capture with expiration on May 29 (Supplementary Tables S11 and S12). The initial illustrations used 1,000 stock paths per ticker and a separate IV factor for each contract under the fixed settings in Supplementary Table S10. Each factor followed a moving target supplied by the fitted surface before its IV entered the lattice calculation at the current stock price and remaining maturity. The GS paths showed the expected inverse relation between terminal stock and put payoff and the direct relation between terminal stock and call payoff (Fig. 3). Before expiration, the put and call factors followed different targets as moneyness and calendar days to expiration changed (Fig. 4). Their shared negative return coupling tended to increase factor shocks after lower standardized returns. The corresponding LLY paths demonstrated the same calculation under a different return marginal and higher fitted IV level (Supplementary Figs. S2 and S3). The pathwise Greeks described the associated risk sensitivities through delta approaching the exercise states, gamma concentrating near the strike, and Vega declining toward expiration (Supplementary Figs. S1 and S4). Algorithm 1 describes these illustrations with return shocks standardized across the completed ensemble. The paired ablation used independent pilot constants instead, as described in Section 2.5, to measure the contribution of IV dynamics on shared evaluation paths. Both experiments used surfaces fitted with observations from the scenario period and examined the behavior of the assembled model. They were illustrative scenarios, not forecasts evaluated against later observations; the chronological tests used separate fits and origins.

Algorithm 1 Forward simulation of contract values

Require: JumpHMM marginal; fitted (θ_i, ψ_i) ; contract (K, T) ; trading dates $d_0, \dots, d_L$; calendar DTE $\tau_0, \dots, \tau_L$; (κ, σ_v, ρ) ; S_0 ; r ; N_p paths; LR depth N_{LR} .

Ensure: Stock, variance, IV, and option-value paths.

- 1: Draw N_p JumpHMM stock paths with L trading transitions.
 - 2: Compute $Z_{j,\ell}^S$ by standardizing all simulated one-session log returns as in (11).
 - 3: Draw $Z_{j,\ell}^\perp \sim \mathcal{N}(0, 1)$ once per path and transition; set $Z_{j,\ell}^v \leftarrow \rho Z_{j,\ell}^S + \sqrt{1 - \rho^2} Z_{j,\ell}^\perp$ and reuse it for every contract.
 - 4: **for** contract a and path j **do**
 - 5: $v_{a,0}^{(j)} \leftarrow \theta_i \psi_i(\tau_0, K/S_0)$
 - 6: **for** $\ell = 0$ **to** $L - 1$ **do**
 - 7: $\sigma_{a,\ell}^{(j)} \leftarrow \sqrt{v_{a,\ell}^{(j)}}$
 - 8: $P_{a,\ell}^{(j)} \leftarrow \text{LR}_{N_{\text{LR}}}(S_{j,\ell}, K, \sigma_{a,\ell}^{(j)}, \tau_\ell/365, r)$
 - 9: $\bar{v}_{a,\ell}^{(j)} \leftarrow \theta_i \psi_i(\tau_\ell, K/S_{j,\ell})$
 - 10: Update $v_{a,\ell+1}^{(j)}$ with the hard-floor rule in (13) using $\Delta t = 1/252$.
 - 11: **end for**
 - 12: $P_{a,L}^{(j)} \leftarrow \max\{\phi(S_{j,L} - K), 0\}$, where $\phi = 1$ for a call and $\phi = -1$ for a put.
 - 13: **end for**
 - 14: **return** all paths.
-

Figure 3: Simulated evolution of GS stock prices (a), put values (b), and call values (c) along 1,000 paths between April 28 and May 29, 2026. The fitted surfaces included observations from this scenario period, so these paths illustrate the model rather than an out-of-sample forecast. Time is measured in calendar days from April 28. Black curves show the median at each date, and shaded bands contain the middle 90% of values. Red and blue curves show group medians for paths ranked in the 1st–5th and 95th–99th percentiles of terminal stock price. These summaries are not individual trajectories. Option values are dollars per share and represent the cost of repurchasing the contract for a short seller. Entry premiums were \$16.51 per share for the put and \$16.09 for the call.

Figure 4: Simulated evolution of annualized IV at the GS put strike (a) and call strike (b). These factors belong to the illustrative scenario in Fig. 3. Both panels express IV as percentages on the same vertical scale. Curves show pointwise medians across all 1,000 paths and within the terminal-stock groups defined in Fig. 3; shading shows the 5th–95th percentile band. Time is measured in calendar days from April 28, 2026, and stops before expiration. IV does not enter the expiration payoff.

To measure the contribution of IV dynamics, we compared five variants on identical stock paths for the four scenario contracts. The comparison held contracts, entry premiums, and pricing assumptions fixed so that differences in interim marks could be attributed to the IV module (Section 2.5). After ten trading transitions, the full factor changed marks by a mean absolute \$1.77–\$2.41 per share relative to direct surface evaluation (Supplementary Table S13). These pathwise changes were much larger than the corresponding difference in the GS put’s mean P&L, which was only \$0.05 lower under the full factor with a paired Monte Carlo standard error of \$0.04. Positive and negative differences therefore largely canceled when averaged across paths. Frozen IV and deterministic mean reversion also produced different marks from the direct surface, showing that movement of the target and persistence around it affected valuation even without stochastic shocks. Comparing the coupled and uncoupled factors on the same paths showed how return coupling changed valuation across stock outcomes. For both tickers, short-put P&L declined most on falling-stock paths, while short-call P&L improved most on rising-stock paths (Fig. 5). Coupling also changed the lower tails of short-position P&L. We measured those tails with 5% expected shortfall, defined as mean P&L at or below its 5% quantile, for which more negative values indicate larger simulated losses. Negative coupling moved the GS put’s expected shortfall from $-\$63.24$ under uncoupled factors to $-\$64.86$ under the full factor. The call’s expected shortfall improved from $-\$71.54$ to $-\$69.83$, and the LLY contracts showed the same direction of change (Supplementary Table S13). The full-factor mean absolute mark differences were similar across the three evaluation seeds (Supplementary Table S14). All variants produced identical entry marks and terminal payoffs. The experiment thus located the contribution of IV dynamics in interim valuation and liquidation risk while preserving the stock paths and terminal outcomes.

Figure 5: Effect of return coupling on interim short-option P&L as a function of stock return after ten trading transitions for (a) GS and (b) LLY. Each difference is coupled-factor P&L ($\rho = -0.6$) minus uncoupled-factor P&L ($\rho = 0$) on the same stock path, with the same independent normal innovations. Negative values indicate worse short-position P&L under coupling. The 3,000 paths per ticker are sorted by stock return and divided into ten groups of 300. Symbols show median paired P&L differences at median stock returns; connecting lines guide the eye, and shaded bands span the within-group 25th–75th percentiles. These bands describe variation across paths, not confidence intervals. Red circles denote puts and navy diamonds denote calls. All marks are evaluated on May 12, 2026, with 17 calendar days to expiry.

We examined numerical accuracy and strike consistency to determine how the ablation differences should be interpreted as option prices. Increasing lattice depth from 201 to 401 changed sampled marks by at most \$0.0017 per share, well below the differences among IV variants. No factor reached the variance floor in the four scenario contracts. Current strike/spot nevertheless left the training interval on 0.7–2.9% of pre-expiry path dates across ticker, contract, and seed combinations, so some marks used extrapolated surface values. The strike audit then tested necessary conditions across separately priced contracts. At 401 lattice steps, the direct GS surface exceeded the \$0.01 convexity tolerance in 178 of 1,818 tested strike triples (Supplementary Table S15). Its largest excess

was \$0.113 per share. The full factor had three monotonicity violations among 2,020 adjacent-strike comparisons, with a maximum of \$0.013. These violations persisted at the higher lattice depth, while no LLY variant violated the tested conditions at the stated tolerance. The checks therefore distinguished two issues in the calculation. The sampled ablation effects exceeded the changes from numerical refinement, but single-contract lattice accuracy did not ensure consistency across strikes. The residual GS violations limited the interpretation of the generated prices as market-consistent training data even though the same outputs supported controlled comparisons of IV assumptions.

We used the terminal results to describe the consequences of the selected stock-return models, strikes, and entry premiums (Supplementary Tables S11 and S12). For a position held to expiration, terminal P&L was the entry premium minus the payoff determined by the final stock price and strike. In GS, the short put retained its full premium on 74.0% of paths and the short call did so on 67.6%. Frequent premium retention nevertheless coexisted with substantial losses: the worst 5% of put outcomes lost at least \$58.92 per share, and the corresponding call threshold was \$86.24. Those less frequent losses left mean P&L positive for the put but negative for the call. The market-delta heuristic $1 - |\Delta|$ gave premium-retention estimates of 70.5% and 67.2% for the same contracts. The LLY put and call retained their premiums on 80.7% and 79.3% of paths, respectively, and both had positive mean P&L under the scenario assumptions. These retention frequencies exceeded the heuristic by 11.0 and 10.2 percentage points. The larger gaps than in GS showed that agreement between the heuristic and simulated strike crossing depended on the ticker and scenario. Quote delta supplied a diagnostic reference from a risk-neutral pricing calculation, whereas the simulated frequencies came from physical stock paths. The terminal results therefore characterized the chosen return distributions and contract inputs. Their independence from interim IV meant that they did not test the fitted surface or the dynamic factor. Evidence for the contribution of IV dynamics came from the paired interim comparisons, which changed the IV module while preserving the stock paths and terminal payoffs.

To examine whether the calibration and simulation results transferred to later observations, we extended the evaluation beyond the original April–May window. The completed expanding-window experiment evaluated two-input sector networks on 53 successive held-out capture dates through July 17. Median test RMSE was 9.92 IV percentage points, but individual folds ranged from 7.68 to 19.25 points (Supplementary Table S16). This spread showed that the pooled surface representation transferred unevenly across dates. Each fold used the later observation’s stock price to determine moneyness, so the result concerned conditional IV prediction rather than a forecast of the stock–option system. We then fitted a single set of sector surfaces through July 31 and evaluated the 23 later sessions from August 4 through September 4. Pooled RMSE increased from 10.79 points in training to 14.75 points in the held-out sample (Supplementary Table S17). These values were not a paired comparison with the earlier folds because the fitting window, capture audit, and evaluation dates differed. The GS surface had held-out RMSE of 6.30 points and mean overprediction of 0.88 points, whereas LLY had RMSE of 9.96 points and mean overprediction of 4.61 points. The larger corpus therefore did not remove the problem of a frozen surface level lagging a later market state. This motivated a separate forecast comparison in which all IV variants started from the observed origin IV and differed in their subsequent evolution (Section 2.6).

The forward evaluation compared forecasts with later observations of the same selected contracts. The maturity-bucket collection scheme imposed an immediate limit: none of the 36 eligible roughly monthly contracts per ticker had an observed exact-symbol endpoint after five sessions (Supplementary Table S18). Their one-session comparison retained 34 quotes across 17 origins per ticker. Coupled-factor MAE was \$3.79 per share for GS and \$6.08 for LLY, compared with \$3.80 and \$6.11 under frozen IV (Supplementary Table S19). The separately identified shorter-maturity cohort supplied five-session outcomes for 34 GS and 30 LLY quotes across 17 origins per ticker. Coupling again produced only small reductions in absolute error of the forecast mean: MAE was \$4.20 versus \$4.22 under frozen IV for GS, and \$11.59 versus \$11.62 for LLY (Table 3). It improved the date-level mean absolute error on six of seventeen GS origins and nine of seventeen LLY origins, so the small average reductions did not show a consistent advantage across dates. Scoring forecast medians separately lowered GS coupled-factor MAE to \$2.48 and gave LLY MAE of \$11.79, with little separation from frozen IV (Supplementary Table S23). The coupled model’s CRPS was 2.01 for GS and 8.93 for LLY, compared with 2.02 and 8.99 under frozen IV. Central 90% intervals had date-weighted coverage of 100% for GS and 67.6% for LLY, with average widths of \$25.65 and \$28.92 per share. Broad coverage in GS therefore coexisted with substantial missed coverage in

LLY. The earliest eligible GS example showed nearly coincident coupled and frozen-IV mean forecasts while the observed call value declined below both means (Fig. 6). These results supported a limited chronological case study of the assembled model, but they did not establish a material forecasting advantage from the fixed stochastic factor or validate the original month-long illustrations.

Table 3: Five-session option forecasts for the shorter-maturity cohort, selected with 10–21 calendar DTE at each origin. Scores average matched contracts within each ticker and origin before averaging dates. MAE scores the forecast mean; MAE, CRPS, and central 90% interval width are dollars per share. Coverage is date-weighted. Every IV variant uses the same stock paths, origin IV, and matched quotes.

Ticker	IV variant	Dates	Quotes	MAE	CRPS	Coverage (%)	Width
GS	Frozen IV	17	34	4.22	2.02	100.0	25.64
GS	Direct surface	17	34	4.87	2.16	67.6	24.02
GS	Mean reversion	17	34	4.26	2.02	100.0	25.63
GS	Uncoupled factor	17	34	4.25	2.03	100.0	25.70
GS	Coupled factor	17	34	4.20	2.01	100.0	25.65
LLY	Frozen IV	17	30	11.62	8.99	73.5	28.99
LLY	Direct surface	17	30	11.62	9.05	55.9	26.69
LLY	Mean reversion	17	30	11.63	8.99	73.5	28.84
LLY	Uncoupled factor	17	30	11.61	8.97	73.5	28.83
LLY	Coupled factor	17	30	11.59	8.93	67.6	28.92

Figure 6: Five-session forecasts of GS stock prices (a), put values (b), and call values (c), compared with observations from August 4 to August 11, 2026. The put strike is \$1,000, the call strike is \$1,105, and both contracts expire on August 21. Forecasts use the July-cutoff surface and information available at the August 4 origin. Navy curves show forecast means from 1,000 stock paths, with the coupled IV factor used for option values; shading spans the central 90% of simulated values. Red dashed curves show frozen-IV mean option forecasts on the same stock paths. Black points show observed stock closes and option midpoints, with vertical bars spanning the observed bid and ask. Time is measured in exchange sessions from the origin. This is the earliest GS origin with both selected shorter-maturity contracts observed at the five-session endpoint.

We used the observed-stock diagnostic to distinguish stock-path errors from the IV and pricing components on a common subset. Complete intervening stock observations were available for thirteen five-session origins per ticker, with 26 matched GS quotes and 24 LLY quotes. On these same cases, replacing simulated stock paths with the observed path reduced coupled-factor MAE from \$4.63 to \$1.23 per share for GS and from \$10.61 to \$1.95 for LLY. The observed path was supplied after the forecast period and would have been unknown at the origin. This calculation diagnosed error sources; it was not an attainable improvement to the forward forecast. Within that diagnostic, frozen IV had lower point errors of \$1.07 and \$1.74, while uncoupled stochastic factors had lower CRPS

than the coupled factor for both tickers (Supplementary Table S20). The stock comparison also gave no point-forecast advantage to the retained JumpHMM settings: five-session stock MAE was \$16.87 for GS and \$49.83 for LLY, versus \$16.17 and \$48.64 for the simple random walk (Supplementary Table S21). Repricing the shorter-maturity endpoint observations with their reported IV reduced five-session option MAE to \$0.14 for GS and \$0.34 for LLY, and those prices lay within every observed bid–ask interval (Supplementary Table S22). Sampled lattice refinement changed marks by at most \$0.0027 per share across the two cohorts, well below the forecast errors. Together, these diagnostics showed that stock-forecast errors contributed substantially to the option-price misses, with additional error remaining in the IV and pricing inputs. They did not establish why the stock estimator missed or how to correct it. They did not identify a reliably superior dynamic variant. The small, overlapping set of origins, missing contract histories, fixed parameters, and absence of quote-level exchange timestamps limited broader conclusions about forecasting accuracy or executable trading performance.

The reduction in option errors after supplying the observed stock path raised a separate question: could a change to the stock forecast improve predictions without using future information? Return-scaling checks and reconstruction of the saved paths found no error in the conversion from annualized log growth to daily prices. Conditioning the initial state on recent returns also did not materially improve five-session central forecasts. Median-based stock MAE changed from \$16.28 to \$16.35 for GS and from \$49.58 to \$49.24 for LLY in that diagnostic (Supplementary Table S24). The effect of the initial state on the forecast distribution largely disappeared within a few sessions under the fitted transitions. We then compared the retained JumpHMM with unchanged-price, adaptive-volatility, and simple directional benchmarks, using earlier data to select the new models’ settings. Validation across 2019–2024 selected an EWMA decay of 0.97 and the zero-drift limit of the directional regression (Supplementary Table S25). The selected directional and adaptive forecasts were consequently identical. The stock and SPY return features did not justify a directional adjustment under this selection criterion. Testing the frozen models in 2025 supplied 245 five-session origins per ticker, substantially more than the 17 available in the 2026 case study. Across these comparisons, central price errors remained close to the unchanged-price benchmark (Table 4). These results did not establish a repair for the large stock-price misses or a consistent central-forecast advantage from the added predictors.

Table 4: Five-session stock forecasts in 2025 and August–September 2026. Each ticker has 245 origins in 2025 and 17 in 2026. MAE scores the forecast median; MAE, CRPS, and central 90% interval width are dollars per share. Scores average dates within each of three 10,000-path replicates and then average replicates. Adaptive denotes the Gaussian model with historically selected EWMA decay 0.97. Historical selection chose zero directional drift, making the selected directional model identical to Adaptive. The unchanged-price benchmark has no uncertainty interval.

Year	Stock	Model	Median MAE	CRPS	Coverage (%)	Width
2025	GS	JumpHMM	22.31	16.22	84.4	84.72
2025	GS	Unchanged	22.61	22.61	–	–
2025	GS	Adaptive	22.62	16.32	89.8	94.86
2025	LLY	JumpHMM	39.10	29.60	69.9	100.41
2025	LLY	Unchanged	39.37	39.37	–	–
2025	LLY	Adaptive	39.35	28.57	84.4	151.37
2026	GS	JumpHMM	16.25	13.03	100.0	129.06
2026	GS	Unchanged	15.51	15.51	–	–
2026	GS	Adaptive	15.48	15.58	100.0	176.18
2026	LLY	JumpHMM	49.44	35.60	70.6	147.27
2026	LLY	Unchanged	49.37	49.37	–	–
2026	LLY	Adaptive	49.31	33.81	94.1	191.38

The stock-distribution comparison nevertheless identified a narrower benefit from adaptive volatility. In 2025, LLY’s five-session CRPS fell from 29.60 under JumpHMM to 28.57 under the adaptive model, while central 90% coverage increased from 69.9% to 84.4%. Average interval width in-

creased from \$100.41 to \$151.37, so the coverage gain came with a wider range of predicted prices. The lower CRPS indicated that this tradeoff improved the distribution score, although coverage remained below its nominal level. The 2026 comparison showed the same direction of change for LLY: CRPS fell from 35.60 to 33.81 and coverage rose from 70.6% to 94.1% (Table 4). The adaptive model had lower date-level CRPS on 131 of 245 LLY origins in 2025 and ten of seventeen in 2026. For GS, however, CRPS increased slightly in 2025, from 16.22 to 16.32, and more substantially in 2026, from 13.03 to 15.58. Both GS models covered every 2026 endpoint, but the adaptive intervals were wider. Full five-session results, including mean-based RMSE and the identical selected directional forecasts, are given in Supplementary Table S26. The one-session comparison also showed little separation in central price error from an unchanged-price forecast (Supplementary Table S27). The findings therefore supported a ticker-dependent improvement in forecast uncertainty for LLY, not a general improvement in predicting stock-price direction. We retained JumpHMM as the worked example for the IV framework and did not select a replacement stock model from these test outcomes.

4 Discussion

In this study, we developed a framework for examining how IV assumptions affect American-option values while retaining a chosen physical stock-return model. The paired ablation established that changing the IV module could alter interim marks and liquidation outcomes on identical stock paths, even though entry marks and terminal payoffs agreed exactly. This was a controlled comparison of model behavior. The chronological evaluation asked the separate question of whether the assembled model predicted later observations accurately. The fixed coupled factor produced only small average reductions in mean-based option forecast error relative to frozen IV, and it did not show a consistent advantage across dates or point summaries. Its central intervals also behaved differently across the two tickers. A more elaborate IV process therefore did not automatically provide a better forecast of future option values. The framework’s demonstrated contribution was the ability to compare these assumptions while preserving the contracts, stock paths, and pricing calculation. That control made both the measured changes and their limits easier to interpret. It also prevented terminal payoff agreement from being mistaken for validation of interim IV dynamics. The construction remains useful for studying how specified stock and IV assumptions affect simulated option values, but agreement within the simulator does not establish agreement with the market. The observed option errors and stock benchmarks were necessary to assess that additional requirement.

The stock evaluation clarified why this distinction mattered for forward use. Replacing simulated stock paths with the subsequently observed paths reduced option errors on the same contracts and dates, but supplied information unavailable when a forecast would have been issued. This diagnostic identified an important contribution from the stock forecast; it did not offer a usable correction or establish the cause of the stock misses. The subsequent stock-only tests found no return-scaling error, and conditioning the initial state on recent returns did not materially improve five-session central forecasts. The fitted transitions quickly lost information about the initial return state. A larger comparison in 2025 then showed central errors close to an unchanged-price benchmark, while earlier validation preferred zero drift for the tested directional regression. These findings concerned the specified models and inputs, not the general possibility of predicting returns. Adaptive volatility improved LLY’s distribution score in both evaluation periods, but did so through a different range of possible prices rather than a learned directional forecast. Its poorer GS scores showed why a wider interval could not be treated as an improvement by itself. The evidence thus supported a limited, ticker-dependent change in uncertainty estimates. It did not justify replacing the stock generator throughout the framework or treating its central projections as reliable predictions of future direction. We retained JumpHMM as the worked example and reported the alternatives as benchmarks.

Separating the stock and IV components also left structural requirements that forecast comparisons could not resolve. A lattice can account for early exercise in an individual contract without ensuring consistent values across strikes. The residual GS violations demonstrated this limitation even under direct evaluation of the fitted surface (Supplementary Table S15). For a strategy involving several contracts, those inconsistencies matter because decisions depend on relative prices as well as the value of each position. Arbitrage-constrained surface methods offer one way to address that requirement before outputs are used as market-consistent training data Cont and Vuletić [2023]. Surface calibration posed another issue. The neural models improved pooled IV fit, yet the May

11 MSFT and LLY panels exposed substantial errors in the date-specific level. The larger July-cutoff fit retained a related problem on later observations. Pooling more dates did not itself supply a mechanism for updating a frozen ticker level. Origin anchoring removed the initial level difference from the forecast comparison, but was an explicit change in initialization and did not impose cross-contract consistency. Repricing with reported endpoint IV further reduced errors for the examined contracts, although it again used later information. Agreement with their quoted spreads did not establish universal compatibility between Alpaca’s Black–Scholes IV field and an American lattice. Surface error, stock-distribution accuracy, option-price error, and strike consistency therefore remained distinct requirements. Improving one did not establish the others or supply the joint pricing interpretation of a calibrated stock-volatility model.

The evidence remains limited by the observation windows, contract availability, and scope of model selection. The initial surface comparisons used fifteen snapshots, and the temporal extensions used one fixed neural training seed. The option forecast test covered 23 capture sessions, while the additional stock-only test supplied a full 2025 observation period. The latter did not extend the option validation to 2025. Overlapping horizons and common market movements reduced the independent information in both evaluations; additional simulated paths did not add market observations. Maturity-bucket collection left the originally selected monthly contracts without five-session endpoints. The shorter-maturity cohort was added after an availability audit and did not validate the original month-long illustrations. The stock benchmark classes were proposed after inspecting the 2026 misses, although their settings were selected using earlier data. The tested predictors and penalties were deliberately limited, and no general superiority claim followed from them. The original JumpHMM, IV-factor parameters, and return coupling remained fixed, while the strike audit covered a finite grid and did not establish calendar or dynamic no-arbitrage. Valuation omitted dividends, execution costs, margin, premium financing, hedging, and prior assignment. Retrieval timestamps did not establish exact stock–option synchronization, and state- and mood-dependent IV mechanisms remained inactive. These limits bound the present use of the framework to controlled modeling comparisons and the specific forecasting evidence reported here. Consistent contract histories and further evaluation across market conditions are needed before drawing broader conclusions about practical trading use.

5 Conclusion

In this study, we developed a computational framework that supplied evolving IV inputs for American-option valuation along separately generated stock paths. Fitted neural surfaces set contract-specific variance targets, and square-root factors translated those targets into lattice inputs. Greater surface flexibility and narrower parameter sharing improved calibration fit, while chronological evaluation exposed uneven transfer to later observations. The paired ablation showed that changing the IV process altered interim marks and liquidation outcomes on identical stock scenarios, with terminal payoffs remaining fixed. The later option forecasts did not establish a consistent advantage for the coupled factor over frozen IV. Supplying subsequently observed stock paths reduced option errors in a diagnostic that used future information, which motivated a separate examination of the stock forecasts. The larger 2025 stock comparison and the 2026 case study showed central errors close to an unchanged-price benchmark. Adaptive volatility improved LLY’s distribution scores in both periods but not GS’s, and earlier validation did not support a directional adjustment from the tested return features. These findings support the framework as a reproducible way to compare IV and stock assumptions, while limiting claims about their forecasting accuracy. The original JumpHMM remains the worked example rather than a newly revised stock estimator. Saved observations, fitted models, simulation outputs, and scoring code make the comparisons reviewable. Incomplete monthly contract histories, dependent evaluation dates, limited model selection, and residual strike inconsistencies remain constraints on broader use.

A Interpretation of the Contract Variance Factor

The scenario model assigned a variance state to each contract rather than one instantaneous variance state to the underlying. The following continuous-time process motivated the Euler update for a fixed target:

$$dv_{a,t} = \kappa(\bar{v}_{a,t} - v_{a,t}) dt + \sigma_v \sqrt{v_{a,t}} dW_{a,t}. \quad (19)$$

Contract a indexes ticker, strike, and expiration. The target $\bar{v}_{a,t}$ in (8) changes with current money-ness and calendar DTE. If that target were held fixed and a stationary distribution existed, its mean would equal $\bar{v}_a$. In the implemented scenario, however, the target moved at every trading date and the hard floor in (13) altered the unconstrained square-root process. We therefore use the stationary result only as motivation for mean reversion, not as a claim about the simulated distribution. At entry, $v_{a,0} = \bar{v}_{a,0}$ reproduces the fitted IV product exactly. Thereafter, $\sigma_{a,t}^2 = v_{a,t}$ supplies the lattice input. The fitted level and neural shape are not separately identified: shifting a constant between $\ln \theta_i$ and the network output bias leaves $\theta_i \psi_i$ unchanged. This does not change fitted IV or scenario output, but it prevents separate economic interpretation of the two components.

B Calibration Details

The snapshot labels, capture timestamps, and underlying-session dates did not always coincide. Table S1 preserves these fields for the frozen corpus described in the main Results. All dates are in 2026. The May 11 underlying-session snapshot was captured on May 12. Temporal earnings splits followed snapshot-directory labels, and the May 11 holdout followed the underlying-session date. The first snapshot contained 23 tickers and the remaining snapshots contained 31. The [source repository](#) provides experiment drivers and reproduction instructions. Its frozen corpus manifest records each file’s SHA-256 hash and filtered row count. Saved ablation outputs also include pilot constants, path-level marks, numerical audits, and copies of the computational sources so that the reported comparisons can be traced to their inputs.

Table S1: Frozen corpus provenance. Temporal earnings splits used snapshot labels; the May 11 single-date holdout used the underlying-session field. The first snapshot label is April 14 although its underlying close was from April 13.

Snapshot label	Capture date	Underlying session	Rows
04-14-2026	2026-04-14	2026-04-13	18,250
04-15-2026	2026-04-15	2026-04-15	17,711

05-08-2026	2026-05-08	2026-05-08	12,293
05-11-2026	2026-05-12	2026-05-11	14,442

Table S2: Sector partition of the 31-ticker ladder across fifteen snapshots. Counts are filtered observations used in calibration.

Sector	Observations	Tickers
ETF	102,738	IWM, QQQ, SPY
Technology	68,334	AAPL, AMD, AVGO, GOOG, INTC, META, MSFT, MU, NVDA, QCOM
Healthcare	26,387	ABBV, AMGN, BMY, JNJ, LLY, MRNA, PFE, UNH
Financials	17,938	BAC, GS, JPM, WFC
Retail	11,320	TGT, UPS, WMT
Energy	7,832	CVX, OXY, XOM

Table S3: In-sample RMSE by sector, in volatility percentage points. The sector network improved on the global neural network in every group, while technology and healthcare retained the largest errors.

Sector	Parametric	Global NN	Sector NN	Observations
ETF	10.54	8.69	6.10	102,738
Financials	9.05	7.79	6.70	17,938
Energy	9.36	8.24	7.88	7,832
Retail	11.73	10.23	9.50	11,320
Healthcare	13.49	12.71	12.53	26,387
Technology	15.58	15.31	14.47	68,334

Table S4: Largest per-ticker in-sample RMSE reductions among the 29 qualified tickers. In total, 21 qualified tickers improved and eight worsened; the combined per-ticker-plus-fallback model reduced pooled RMSE from 10.24 to 9.73 volatility percentage points. The BMY and PFE fits retained their sector surfaces.

Ticker	Observations	Sector NN	Per-ticker NN	Reduction
JNJ	2,190	11.14	7.17	3.97
MRNA	2,851	17.49	13.74	3.76
AAPL	6,594	14.30	12.59	1.70
INTC	3,417	17.78	16.29	1.49
AMGN	3,383	13.36	12.14	1.21
MU	6,619	18.45	17.26	1.19
NVDA	5,805	10.14	9.15	0.99

Table S5: Mean IV near the money in the May 11 smile panels (Fig. 1). Each row uses the plotted calls and puts with $0.98 \leq K/S \leq 1.02$ at the indicated calendar days to expiry (DTE). Observed and predicted IV are percentages; bias is mean per-ticker predicted IV minus observed IV in percentage points. Predictions use the saved fifteen-date fit evaluated at each observed contract. The NVDA subset contains only two observations.

Ticker	DTE	N	Observed IV	Predicted IV	Bias
SPY	7	52	13.57	13.75	+0.18
NVDA	7	2	38.65	34.02	-4.62
MSFT	9	14	28.47	37.92	+9.45
LLY	11	20	38.59	46.49	+7.90
GS	11	24	32.06	31.74	-0.32
AVGO	9	14	49.08	43.72	-5.37

Table S6: May 11 price-error summary for the contracts plotted in Fig. 2. Dollar errors are absolute differences from the market mid. The per-ticker column used a per-ticker surface where qualified and a sector fallback otherwise; the market-IV reference passed each contract’s reported IV to the same 200-step CRR lattice.

Ticker	DTE	N	Half-spread	Per-ticker error	Inside spread	Market-IV error
SPY	7	176	\$0.03	\$0.12	33%	\$0.01
NVDA	7	34	\$0.04	\$0.13	35%	\$0.12
LLY	11	156	\$2.98	\$4.01	30%	\$0.67
GS	11	145	\$1.56	\$0.46	88%	\$0.12

Table S7: Best and worst ticker-level in-sample RMSE under the sector networks. Errors are in volatility percentage points.

Rank	Ticker	Observations	RMSE	Sector
<i>Best five</i>				
1	GS	8,772	5.40	Financials
2	SPY	42,224	6.02	ETF
3	IWM	21,368	6.11	ETF
4	QQQ	39,146	6.17	ETF
5	JPM	3,720	6.18	Financials
<i>Worst five</i>				
27	PFE	1,300	17.66	Healthcare
28	AMD	4,566	17.74	Technology
29	INTC	3,417	17.78	Technology
30	MU	6,619	18.45	Technology
31	QCOM	3,375	21.46	Technology

B.1 Single-date holdout

We held out May 11, 2026, to examine whether the sector surfaces transferred to a nearby date within the observed period. We retrained on the other fourteen dates and calculated input-standardization constants from those training rows alone. Pooled test error exceeded training error by 0.68 volatility percentage points (Table S8). Energy and retail had larger positive gaps, indicating poorer transfer for those groups in this split. The pooled result therefore concealed differences in performance across sectors. This analysis used one held-out date and one training seed. It described transfer within the available observation window and did not test stability across repeated training runs or different market regimes.

Table S8: Sector-network RMSE after fitting on fourteen dates and holding out the 14,442 observations from May 11, 2026. Values and test-minus-train gaps are in volatility percentage points.

Sector	Train	Test	Gap
ETF	6.12	5.87	−0.25
Financials	6.72	6.32	−0.40
Healthcare	12.58	12.00	−0.58
Technology	14.45	15.04	+0.58
Energy	7.74	9.97	+2.23
Retail	9.21	13.17	+3.96
Pooled	10.21	10.89	+0.68

C Earnings-Holdout Ticker Results

The technology-ticker breakdown examined whether the pooled improvement from earnings inputs extended across individual tickers. The two-input and four-input models used the same training and test observations. Several tickers with a peer earnings date near the holdout had lower error under the four-input model (Table S9). The improvement was uneven, and INTC and NVDA had higher errors. This pattern was consistent with useful calendar information in the pooled fit. Both ticker and peer distances were added together, so the comparison did not isolate the contribution of either input. Calendar distance also contained no information about the sign or magnitude of a realized earnings surprise. The ticker results therefore described variation within this particular temporal split.

Table S9: Technology-ticker test RMSE for the pooled model (A) and earnings-aware model (C). Inputs e and e^{peer} are median signed ticker distance and minimum peer distance, in days. Error differences are in volatility percentage points.

Ticker	e	e^{peer}	A: pooled	C: event inputs	Difference
QCOM	+5	1	41.66	37.59	−4.07
AMD	+11	1	40.07	36.50	−3.57
META	+5	1	14.32	10.73	−3.59
MSFT	+5	1	14.00	10.73	−3.28
GOOG	+5	1	9.87	7.90	−1.97
MU	−30	1	16.95	15.59	−1.36
AAPL	+6	1	10.42	10.34	−0.08
AVGO	+30	1	12.58	12.83	+0.24
NVDA	+26	1	9.43	10.47	+1.05
INTC	−1	5	33.17	35.94	+2.77

D Scenario Statistics and Greeks

The fitted illustrations used a common simulation design to compare contract outcomes under two stock-return marginals (Table S10). For GS, frequent retention of the entry premium coexisted with substantial lower-tail losses (Table S11). The 5% expected shortfall summarized those losses as the mean P&L at or below the empirical 5% quantile. More negative values indicated worse simulated tails. The premium-retained interval was a two-sided 95% Wilson interval for the fraction of paths that expired out of the money. That interval described sampling uncertainty in the simulated frequency conditional on the chosen return model. It did not measure uncertainty in the fitted return distribution or the accuracy of the simulation against future market outcomes.

Table S10: Fixed simulation design shared by the GS and LLY fitted illustrations.

Setting	Value
Simulation paths	1,000
Random seed	20260429
Horizon	April 28–May 29, 2026
Calendar days	31
Trading transitions	22
Annual mean-growth prior	10%
Mean-reversion rate κ	15
Factor volatility σ_v	0.5
Return–factor coupling ρ	−0.6
Risk-free rate r	4.25%
Dividend yield q	0
Leisen–Reimer depth	201

Table S11: Scenario results for GS from 1,000 paths between April 28 and May 29, 2026. The horizon had 31 calendar days and 22 trading transitions. Dollar option values and P&L are per share.

Statistic	Short put	Short call
Initial spot	926.38	
Strike	890.00	970.00
Market delta	-0.295	+0.328
Market IV	31.2%	28.9%
Market mid	16.51	16.09
Model entry value	17.26	16.07
Model value minus market mid	0.75	-0.02
Mean P&L	4.27	-2.21
Monte Carlo SE of mean	0.89	1.23
Median P&L	16.51	16.09
Standard deviation	28.18	38.89
5% quantile	-58.92	-86.24
5% expected shortfall	-92.96	-130.83
Premium retained	74.0%	67.6%
Wilson 95% interval	71.2–76.6%	64.6–70.4%
Delta-heuristic premium retained	70.5%	67.2%
Simulated minus heuristic	+3.5 pp	+0.4 pp

We calculated Greeks along each path to describe how interim option values responded to changes in pricing inputs. The calculation used central finite differences of the same Leisen–Reimer function that supplied the base mark (Algorithm 2). Delta measured price sensitivity to spot, and gamma measured the change in delta with spot. Vega measured sensitivity to volatility and was reported per one volatility percentage point. The GS paths showed delta approaching the terminal exercise states, gamma concentrating near the strike, and Vega declining toward zero (Fig. S1). These sensitivities used the long-option convention. The corresponding short-position Greeks had the opposite sign because the short seller owed the option value.

Algorithm 2 Path-conditional Greeks by central finite differences

Require: State (S, σ, τ) ; contract (K, r) ; LR depth N_{LR} ; relative spot bump h_S ; absolute IV bump h_σ .

Ensure: Δ , Γ , and Vega.

- 1: $P_+^S \leftarrow \text{LR}(S(1 + h_S), K, \sigma, \tau, r)$ and $P_-^S \leftarrow \text{LR}(S(1 - h_S), K, \sigma, \tau, r)$.
 - 2: $P_0 \leftarrow \text{LR}(S, K, \sigma, \tau, r)$.
 - 3: $P_+^\sigma \leftarrow \text{LR}(S, K, \sigma + h_\sigma, \tau, r)$ and $P_-^\sigma \leftarrow \text{LR}(S, K, \sigma - h_\sigma, \tau, r)$.
 - 4: $\Delta \leftarrow (P_+^S - P_-^S)/(2h_S S)$.
 - 5: $\Gamma \leftarrow (P_+^S - 2P_0 + P_-^S)/(h_S S)^2$.
 - 6: $\text{Vega} \leftarrow 0.01(P_+^\sigma - P_-^\sigma)/(2h_\sigma)$.
 - 7: **return** $(\Delta, \Gamma, \text{Vega})$.
-

Figure S1: Simulated evolution of GS long-option delta, gamma, and Vega along the stock paths. Sensitivities are calculated with the 201-step Leisen-Reimer pricer. Spot bumps were 1.5% of spot, and IV bumps were 0.005. Vega is dollars per one volatility percentage point.

Table S12: Scenario results for LLY from 1,000 paths between April 28 and May 29, 2026. The horizon had 31 calendar days and 22 trading transitions. Dollar option values and P&L are per share.

Statistic	Short put	Short call
Initial spot	873.83	
Strike	825.00	940.00
Market delta	-0.303	+0.309
Market IV	44.4%	44.0%
Market mid	23.30	20.76
Model entry value	21.95	18.96
Model value minus market mid	-1.35	-1.80
Mean P&L	16.36	10.60
Monte Carlo SE of mean	0.63	0.91
Median P&L	23.30	20.76
Standard deviation	19.93	28.67
5% quantile	-27.96	-52.01
5% expected shortfall	-57.16	-94.23
Premium retained	80.7%	79.3%
Wilson 95% interval	78.1–83.0%	76.7–81.7%
Delta-heuristic premium retained	69.7%	69.1%
Simulated minus heuristic	+11.0 pp	+10.2 pp

Figure S2: Simulated evolution of LLY stock prices (a), put values (b), and call values (c) along 1,000 paths between April 28 and May 29, 2026. The fitted surfaces included observations from this scenario period; these are illustrative paths, not an out-of-sample forecast. Time is measured in calendar days from April 28. Black curves show pointwise medians, and shading contains the middle 90% of values. Red and blue curves show group medians for the 1st–5th and 95th–99th terminal-stock percentiles. Option values are dollars per share and represent repurchase costs for a short seller. Entry premiums were \$23.30 per share for the put and \$20.76 for the call.

Figure S3: Simulated evolution of annualized IV at the LLY put strike (a) and call strike (b). Both panels express IV as percentages on the same vertical scale. Curves show pointwise medians across all 1,000 paths and within the terminal-stock groups in Supplementary Fig. S2; shading shows the 5th–95th percentile band. Time is measured in calendar days from April 28, 2026, and stops before expiration, when IV no longer enters the payoff.

Figure S4: Simulated evolution of LLY long-option delta, gamma, and Vega along the stock paths. Sensitivities are calculated with the 201-step Leisen-Reimer pricer. Short-position Greeks have the opposite sign.

E Dynamic Ablation and Strike Diagnostics

The primary ten-transition endpoint compared liquidation outcomes across IV variants on shared stock paths (Table S13). Mean absolute mark differences measured how much the prices changed along individual paths. Paired mean P&L differences showed how those changes combined across the ensemble. The three evaluation seeds provided separate realizations of the comparison under the same fitted models and pilot constants (Table S14). Expected shortfalls summarized the simulated lower tails of P&L. The paired standard errors applied to mean differences and did not supply uncertainty intervals for expected shortfall. All reported uncertainty was conditional on the fitted surface and pilot normalization constants. Variation from refitting either component remained outside these estimates.

Table S13: Liquidation after ten trading transitions (May 12, 2026), with 17 calendar DTE. Each row uses 3,000 paths. All monetary quantities are dollars per share. $\Delta P\&L$ and mean $|\Delta P|$ compare the variant with the direct-surface reference on identical paths. Parentheses contain the paired Monte Carlo standard error of mean $\Delta P\&L$. More negative 5% expected shortfall indicates a worse simulated lower tail.

Contract	IV variant	Mean P&L	ES _{5%}	$\Delta P\&L$ (SE)	Mean $ \Delta P $
GS put	Frozen IV	0.66	-63.34	+0.29 (0.01)	0.51

Table S15 reports the necessary strike-condition checks at 401 steps. The grid had eleven fixed strikes at the scenario expiry, with fifty stock paths evaluated after ten and twenty transitions plus one shared entry state. As spot moved, some fixed strikes left the calibration moneyness interval; the audit therefore included extrapolated states. Each variant and ticker supplied 2,222 bound checks, 2,020 adjacent-strike checks, and 1,818 convexity checks across calls and puts. The companion machine-readable output reports both lattice depths, each test location, and the violation magnitude. Passing this finite grid does not establish the absence of arbitrage elsewhere or consistency across maturities.

Table S15: Strike-condition violations exceeding \$0.01 per share at 401 lattice steps. Entries show violations/tests. Vertical denotes the upper bound on an adjacent-strike option-price difference. Max reports the largest positive deviation across the four checks, including deviations below the reporting tolerance.

F Chronological Evaluation Details

The completed expanding-window experiment tested conditional surface transfer across 53 successive capture-date splits. Its two-input sector networks used moneyness and maturity from each later observation, including that observation’s stock price. Table S16 reports the distribution of fold RMSE by test month. The new July-cutoff experiment used a larger training window, stricter capture handling, recomputed calendar DTE, and a later test period. Its pooled sector errors are reported separately in Table S17, so they are not interpreted as a paired comparison with the earlier folds. Both analyses used one fixed neural training seed and did not quantify uncertainty from refitting with other seeds.

Table S16: Chronological sector-surface prediction errors across 53 expanding-window folds. Each fold fitted earlier capture dates and evaluated the next captured date using its observed stock price. RMSE is in IV percentage points.

Test month	Folds	Median RMSE	Minimum	Maximum
April	6	12.72	7.79	17.45
May	17	9.62	8.65	11.30
June	18	10.02	8.55	19.25
July	12	9.76	7.68	10.51

Table S17: Training and held-out IV errors for sector surfaces frozen at the July 31 cutoff. Training used 68 underlying sessions; testing used 23 later sessions from August 4 through September 4. Each RMSE pools observations within the indicated sector. Bias is predicted minus observed IV, in percentage points.

Sector	Train rows	Test rows	Train RMSE	Test RMSE	Test bias
ETF	503,487	186,987	7.03	6.59	+3.08
Financials	83,005	27,853	7.40	7.81	+2.50
Energy	34,817	10,956	8.15	9.40	+2.45
Retail	50,776	15,096	10.02	11.77	+1.83
Healthcare	126,818	45,472	12.14	12.21	+3.77
Tech	374,635	138,697	14.70	22.91	+14.81
Pooled	1,173,538	425,061	10.79	14.75	+6.88

The origin rule selected contracts before looking for later matches. Table S18 distinguishes selected forecasts whose endpoint fell inside the fixed window from those with valid exact-symbol endpoint quotes. The monthly cohort used 25–45 calendar DTE and selected expiry nearest 31 DTE. The short cohort used 10–21 DTE and selected expiry nearest 14 DTE after the monthly cohort proved unavailable at the five-session horizon. Missing endpoint quotes were not replaced, and coverage of the selected universe remained part of the reported result. Full stock-path availability required a recorded underlying close at every intervening exchange session; it was more restrictive than having an endpoint quote. The observed-stock diagnostic therefore had its own sample size and was compared across IV variants only on that common subset.

Table S18: Availability of exact-contract outcomes by cohort, ticker, and horizon. Selected counts include all origin-selected contracts whose endpoint fell within the fixed window, including endpoints on missing capture dates. Full stock path counts selected contracts with all intervening stock observations, whether or not the endpoint option quote was available. Horizons are exchange sessions.

Cohort	Ticker	Horizon	Origins	Selected	Matched	Missing	Full stock path
monthly	GS	1	22	44	34	10	42
monthly	GS	5	18	36	0	36	26

short	GS	5	17	34	0.14	100.0
short	LLY	1	21	41	0.32	100.0
short	LLY	5	17	30	0.34	100.0

Table S23: Five-session option errors under mean and median point forecasts for the shorter-maturity cohort. Mean MAE and Mean RMSE score the simulated mean; Median MAE scores the median. All errors are dollars per share and use the same date-weighted contracts as Table 3. The prespecified mean-based comparison is retained alongside the additional point summaries.

Stock	IV variant	Mean MAE	Median MAE	Mean RMSE
GS	Frozen IV	4.22	2.49	5.06
GS	Direct surface	4.87	2.62	5.62
GS	Mean reversion	4.26	2.50	5.10
GS	Uncoupled factor	4.25	2.48	5.08
GS	Coupled factor	4.20	2.48	4.99
LLY	Frozen IV	11.62	11.78	15.00
LLY	Direct surface	11.62	11.59	14.74
LLY	Mean reversion	11.63	11.77	14.98
LLY	Uncoupled factor	11.61	11.80	14.97
LLY	Coupled factor	11.59	11.79	14.92

We checked numerical calculations separately from agreement with market observations. Recomputing prices from the saved stock and variance paths reproduced the forecast means, quantiles, and CRPS. Increasing lattice depth from 201 to 401 steps in the sampled checks changed prices by at most \$0.0027 per share. At the first origin for each ticker, paired Monte Carlo standard errors for coupled-minus-frozen mean prices ranged from \$0.041 to \$0.061 across the four shorter-maturity five-session contracts. These errors described simulation precision for individual price differences; they were not confidence intervals for average forecast accuracy across market dates. The small aggregate MAE reductions therefore did not justify a claim of predictive superiority. In the observed-stock diagnostic, frozen IV, direct surface evaluation, and deterministic mean reversion produced a single price once the stock path was supplied, so their central intervals had zero width. Stochastic-factor intervals retained only IV uncertainty. Their coverage in Table S20 consequently answered a different question from coverage of the joint stock–option forecasts. The saved score files include both cohorts, both horizons where outcomes were available, all five IV variants, and the date-level errors used in aggregation.

G Stock Forecast Evaluation

The stock evaluation separated a check of the existing generator from the comparison of new benchmarks. The saved GS and LLY marginals used daily steps of $1/252$ year and annualized excess log returns. Reconstructing the first-origin forecasts reproduced the saved stock means at both one and five sessions. The original simulator drew the first return state from the stationary distribution, without conditioning on recent returns. In the initialization check, we inferred the current state from available daily returns and advanced it before generating the first future return. The inference tracked both the return state and the number of forced tail-state emissions remaining in a jump episode. Poisson durations retained all but at most 10^{-12} probability, with the remaining mass assigned to the

final duration. Missing daily observations advanced the latent distribution without an observation likelihood; an accumulated multi-day return was not treated as a daily observation. The fixed pilot growth shift was removed from observed annualized returns when calculating likelihoods, consistent with the simulated observation model. Table S24 compares this conditional initialization with the original start on the same 2026 endpoints. Both used three 10,000-path replicates, with seeds separate from the subsequent four-method benchmark. The original return-state distributions mixed rapidly under the fitted transitions, so the initial-state adjustment had little effect on five-session central forecasts. The broader exploratory checks, including a fixed 20-return volatility adjustment and Gaussian random walks, are retained in the saved experiment outputs.

Table S24: Stock forecast errors under original and history-conditioned initialization on identical 2026 endpoints. Each ticker has 21 one-session and 17 five-session origins. MAE scores the forecast median; errors are dollars per share and average three 10,000-path replicates. Filtered denotes initialization from available past returns, including inference of remaining jump duration.

Stock	Horizon	Original MAE	Filtered MAE	Original CRPS	Filtered CRPS
GS	1	10.64	10.76	7.99	8.41
GS	5	16.28	16.35	12.99	13.19
LLY	1	19.10	19.09	14.73	14.64
LLY	5	49.58	49.24	35.69	35.28

The benchmark comparison retained the original generator and tested one adaptive variance rule and one directional model against it. For each annual validation block from 2019 through 2024, regression training responses ended before the validation year and validation endpoints remained within it. The EWMA variance began with the sample variance of the first sixty training daily returns and then updated using only returns observed by each origin. Decay selection minimized $\frac{1}{2}[\log(ha_t) + y_{t,h}^2/(ha_t)]$, where $y_{t,h}$ was the observed cumulative log return over h sessions. We first averaged this loss within each ticker, validation year, and horizon, then gave the resulting groups equal weight. With the selected decay, the regression fitted the next daily return divided by origin volatility. Its four features were the stock’s last daily return, its last five- and twenty-return sums, and SPY’s last five-return sum. Return sums were divided by the corresponding origin volatility and square root of window length; feature columns were further divided by their training root mean square. The ridge objective was mean squared normalized one-session error plus the penalty times the squared coefficient norm. There was no intercept. Penalty selection used $(y_{t,h} - h\hat{\mu}_t)^2/(ha_t)$, with the same group weighting as decay selection. Table S25 gives every candidate’s validation loss. The selected zero-drift limit set all four coefficients to zero for both tickers. Final coefficients and feature scales were fitted using 2014–2024 only and saved before evaluating test forecasts. The two selection losses answer different questions and are not comparable in magnitude.

Table S25: Earlier-data selection of adaptive-volatility and directional-model settings. Losses average ticker, year, and horizon groups equally across 2019–2024 validation blocks. Lower values are better within each selection task. EWMA decay 0.97 and the zero-drift limit were selected; 2025 and 2026 outcomes did not enter these choices.

Selection	Setting	Validation loss
EWMA decay	0.80	-2.921492
EWMA decay	0.90	-3.009741
EWMA decay	0.94	-3.044490
EWMA decay	0.97	-3.065558
EWMA decay	0.99	-3.064379
Ridge penalty	0.01	1.146523
Ridge penalty	0.1	1.143850
Ridge penalty	1	1.138475
Ridge penalty	10	1.136428
Ridge penalty	100	1.136142
Ridge penalty	1000	1.136112
Ridge penalty	Zero drift	1.136109

Historical close series for GS, LLY, and SPY shared the same recorded session grid, with 2,767 closes per ticker in 2014–2024 and 250 in 2025. The 2025 test updated lag features and variance using information through each origin while keeping fitted parameters fixed. The 2026 series began in April after a data gap. Its variance restarted from the 2014–2024 sample estimate and updated through the available April–July daily returns before evaluation. December 2025 and April 2026 were not joined into a daily return. Within 2026, both adjacent exchange-session closes were required to calculate a daily return; missing observations left variance unchanged. Feature windows used the last required number of valid daily returns, which could span more sessions when observations were missing. The oldest feature input at an evaluated 2026 origin was four calendar days old, whereas the 2025 features had no such gap. Every method used the same observed starting price and endpoint, and none used option quotes. Tables S26 and S27 retain all four candidates and both evaluation periods. The directional and adaptive rows agree exactly because zero drift was selected. Their small median-error differences from the unchanged-price benchmark arise from Monte Carlo estimation of a distribution whose population median equals the origin price. They are not a learned directional effect. Replicate scores, date-level comparisons, input hashes, and settings are retained with the experiment. Overlapping horizons imply dependent observations, and the three simulation seeds measure simulation variation rather than three independent market samples.

Table S26: Complete five-session stock forecast scores for the four selected candidates. Each ticker has 245 origins in 2025 and 17 in August–September 2026. MAE scores medians and RMSE scores means. Monetary quantities are dollars per share; coverage and width describe central 90% intervals. Scores average dates within each of three 10,000-path replicates and then average replicates. Directional equals Adaptive because earlier-data selection chose zero drift.

Year	Stock	Model	Median MAE	Mean RMSE	CRPS	Coverage (%)	Width
2025	GS	JumpHMM	22.31	28.42	16.22	84.4	84.72
