Abstract

Many American-option lattices require implied volatility (IV), which is recovered from an observed option price. We present a pipeline that fits IV offline and simulates option markets without contemporaneous quotes. A Jump Hidden Markov Model generates stock paths. A neural surface sets contract variance targets from calendar maturity and moneyness. Square-root factors evolve around those targets, and a lattice prices American options and Greeks. The construction is inspired by Heston’s variance process, but it is not a standard Heston model because each contract has its own factor and the stock is generated separately. On 234,549 observations from 31 tickers and fifteen dates, a global neural surface reduced in-sample IV root mean squared error from 12.48 to 11.47 volatility percentage points; sector networks reached 10.24 points. A single-date split had train and test errors of 10.21 and 10.89 points. On a separate two-day holdout, earnings inputs reduced test error from 13.03 to 11.98 points, although the design did not isolate a causal earnings effect. Fitted Goldman Sachs and Eli Lilly illustrations used 1,000 paths, 31 calendar days, and 22 trading transitions. Dynamic IV determined interim marks and Greeks, while held-to-expiration profit and loss depended only on the JumpHMM terminal stock price and payoff. The implementation is open source.

1 Introduction

Synthetic option markets are useful when the question extends beyond the next stock return. Portfolio stress tests, trading-system studies, and machine-learning experiments may require complete paths of option values and risk sensitivities under market conditions that have not been observed. For American options, those paths must also account for changing time to expiration and the right to exercise before maturity. A plausible stock path is therefore only one part of the problem. The simulation must also assign volatility across strikes and maturities, update that volatility as the path unfolds, and convert each simulated state into an American-option value and Greeks.

The main difficulty is the circular role of market prices and implied volatility (IV) in a common pricing workflow. In observed data, IV is recovered by inverting an option price under a chosen pricing model [Black and Scholes \[1973\]](#). A pricer can then use that IV to reproduce the observed price or interpolate nearby contracts. In a forward simulation, however, the future option quote is precisely what is missing. The model must supply a path-conditional IV before it can calculate the synthetic quote. That IV should respond to changing spot, moneyness, and time to expiration without treating an unobserved future option price as an input. The problem is especially clear when

*Corresponding author.

the desired stock-return process is empirical and non-Gaussian rather than the return process implied by the option-pricing model.

Existing approaches address different parts of this problem. Parametric surfaces such as SABR and SVI summarize observed volatility smiles with a small number of parameters [Hagan et al. \[2002\]](#), [Gatheral \[2004\]](#). Neural surfaces can represent more varied cross-sectional shapes [Horvath et al. \[2021\]](#), [Bayer and Stemper \[2018\]](#). These methods are effective interpolators after they have been fitted, but a fitted surface is static unless the model also specifies how it changes along a simulated path. Local-volatility and stochastic-volatility models instead provide joint dynamics for the stock and its volatility [Dupire \[1994\]](#), [Derman and Kani \[1994\]](#), [Heston \[1993\]](#). They offer a coherent route from calibration to pricing, but they also determine the stock dynamics. That coupling is restrictive when the objective is to retain a separate return generator chosen for empirical tail behavior, volatility clustering, or cross-asset dependence.

Return-first methods have the complementary limitation. Historical and generative return models can reproduce non-Gaussian features of equity data, including heavy tails and volatility clustering [Cont \[2001\]](#), [Wiese et al. \[2020\]](#). A Jump Hidden Markov Model (JumpHMM), for example, represents returns through persistent latent states and explicit visits to tail states [Alswaidan and Varner \[2026\]](#). Such a generator supplies physical stock paths but does not determine an option-implied volatility surface or an American-option value. Recombining lattices solve the early-exercise problem once spot, maturity, rates, and volatility have been supplied [Cox et al. \[1979\]](#), [Leisen and Reimer \[1996\]](#), but the lattice does not generate the volatility input. Thus the return generator, IV model, and option pricer can each be well specified while the synthetic market remains incomplete.

A modular solution should connect these components without obscuring their different roles. Market option data can be used once to fit the cross-sectional IV structure. An empirical generator can then produce stock paths, while a separate dynamic rule updates contract IV around the fitted surface as spot and maturity change. An American-option pricer can translate those states into interim marks and Greeks. This separation also clarifies what each component can explain. The return generator determines the terminal stock distribution and held-to-expiration payoff. The IV process affects interim valuation and risk sensitivities. The lattice supplies the exercise rule conditional on those inputs. None of the three should be interpreted as evidence that the other two have been validated.

In this study, we developed a modular framework for turning empirically generated equity paths into synthetic American-option markets without requiring a contemporaneous option quote at each simulated step. We fitted positive neural IV surfaces offline, used JumpHMM to generate the stock paths, evolved a separate CIR-like square-root IV factor for each contract around its fitted surface target, and priced the resulting states with Cox–Ross–Rubinstein and Leisen–Reimer lattices. We compared global, sector-specific, and per-ticker surface sharing on 234,549 observations from 31 tickers and fifteen dates, and we tested temporal splits with and without earnings-calendar inputs. Fitted Goldman Sachs and Eli Lilly scenarios then demonstrated the full path from simulated returns to IV, option values, Greeks, and terminal profit and loss. These scenarios were computational illustrations rather than out-of-sample trading tests because their surface fits included observations from the same period. The implementation and experiment drivers are available at <https://github.com/varnerlab/heston-implied-volatility-model>. More broadly, the framework makes it possible to replace or test the return generator, IV dynamics, or pricer independently while still producing a complete synthetic option market.

2 Methods

2.1 Pipeline

The generator passed information through three stages. The complete data flow was:

$$\text{JumpHMM stock path} \longrightarrow \text{contract IV factor} \longrightarrow \text{American lattice price and Greeks.} \quad (1)$$

The stages were run forward without feedback from the lattice. Market option data entered only when the IV surface was fitted offline. A simulated step did not require a contemporaneous option quote.

2.2 JumpHMM stock-path generator

The Jump Hidden Markov Model (JumpHMM) was developed to generate equity returns with heavy tails, weak linear autocorrelation, and persistent volatility clustering [Alswaidan and Varner \[2026\]](#), [Cont \[2001\]](#). It discretizes excess growth rates into latent states. Each state emits from a location-scale Student- t distribution, and a jump mechanism increases visits to tail states. A Student- t copula can couple several fitted marginals and preserve cross-asset tail dependence [Demarta and McNeil \[2005\]](#). In this study, the single-ticker scenario drivers used pretrained JumpHMM marginals. JumpHMM determined the stock path and therefore the terminal option payoff.

2.3 Offline IV-surface calibration

SABR and SVI represent IV smiles with low-dimensional parametric functions [Hagan et al. \[2002\]](#), [Gatheral \[2004\]](#). Neural representations can fit a broader range of surface shapes [Horvath et al. \[2021\]](#), [Bayer and Stemper \[2018\]](#), but unconstrained networks do not automatically satisfy static no-arbitrage conditions. We compared a five-parameter log-polynomial with global, sector-specific, and per-ticker neural surfaces. Positivity was enforced by exponentiating the network output. Calendar monotonicity and strike convexity were not imposed, so positivity alone did not establish an arbitrage-free surface.

For ticker i , calendar days to expiration τ , and moneyness $m = K/S$, the parametric surface used the positive shape function:

$$\psi_\beta(\tau, m) = \exp[\beta_1 \ln \tau + \beta_2 \ln m + \beta_3 \ln \tau \ln m + \beta_4 (\ln m)^2 + \beta_5 (\ln \tau)^2]. \quad (2)$$

The corresponding IV prediction was defined by a ticker level and the surface shape:

$$\hat{\sigma}_i^2(\tau, m) = \theta_i \psi(\tau, m), \quad \theta_i > 0, \quad \psi(\tau, m) > 0. \quad (3)$$

This expression is also the observation-day calibration target, which we denote by:

$$\theta_{\text{cal}}(i, \tau, m) = \theta_i \psi(\tau, m). \quad (4)$$

The neural models replaced the log-polynomial with a positive network output. For the two-input fits, the surface was:

$$\psi_{\text{NN}}(\tau, m; w) = \exp[\text{NN}(\text{std}(\ln \tau), \text{std}(\ln m); w)]. \quad (5)$$

Inputs were standardized using the training rows. Networks with at least 5,000 per-ticker observations, or 2,000 pooled group observations, used a $2 \rightarrow 16 \rightarrow 16 \rightarrow 1$ architecture with tanh activations and 337 parameters. Smaller qualified groups used $2 \rightarrow 8 \rightarrow 8 \rightarrow 1$ with 105 parameters.

Network weights and ticker log levels were fitted jointly by minimizing IV mean squared error. The training objective was:

$$\min_{w, \{\ln \theta_i\}} \frac{1}{n} \sum_{j=1}^n \left[\sqrt{\theta_{i(j)} \psi_{\text{NN}}(\tau_j, m_j; w)} - \sigma_{\text{market}, j} \right]^2. \quad (6)$$

The log levels were initialized from each ticker's mean squared market IV. Adam training used a decreasing learning-rate schedule, at most 2,000 epochs, and a best-training-loss checkpoint with patience 200. Because a constant can be shifted between $\ln \theta_i$ and the output bias of the network, these two components are not separately identified. Only their product in (3) is interpretable without an additional normalization constraint.

For the earnings analysis, two standardized inputs were appended: signed days to the ticker's nearest earnings date, clipped to $[-30, 30]$, and the minimum absolute earnings distance among same-sector peers, clipped to 30. The resulting $4 \rightarrow 16 \rightarrow 16 \rightarrow 1$ network had 369 parameters. Earnings dates came from the public Yahoo Finance calendar. These event features were evaluated only in the temporal calibration comparison and were not used in the GS and LLY scenario drivers.

2.4 Contract-specific dynamic IV factors

The standard Heston model couples an asset-price diffusion to a square-root instantaneous-variance process [Heston \[1993\]](#). Its variance equation is:

$$dv_t = \kappa(\theta - v_t) dt + \sigma_v \sqrt{v_t} dW_t^v. \quad (7)$$

Here κ is the mean-reversion rate, θ is long-run variance, and σ_v is volatility of variance. In the standard model, the Brownian motion in (7) is correlated with the Brownian motion that drives the stock.

Our use of (7) was narrower. We retained positive square-root fluctuations and mean reversion, but JumpHMM generated the stock separately. We also evolved one variance state for each contract rather than one instantaneous variance state for the underlying. The process therefore supplied a time-varying diffusion-volatility input to a constant-volatility lattice at each simulated date. It should be interpreted as a CIR-like dynamic IV factor, not as the instantaneous return variance of a standard Heston economy.

Each scenario contract $a = (i, K, T)$ received a separate variance state $v_{a,t}$. Its moving mean-reversion target used the fitted surface at the current spot and remaining calendar DTE. The target was:

$$\bar{v}_{a,t} = \theta_i \psi_{\text{NN}}(\tau_t, K/S_t). \quad (8)$$

The factor started exactly on the fitted entry surface:

$$v_{a,0} = \bar{v}_{a,0}. \quad (9)$$

At each later date, the lattice IV was the square root of that contract's factor:

$$\sigma_{a,t} = \sqrt{v_{a,t}}. \quad (10)$$

Thus a put and call on the same stock shared the stock path and variance shock but retained different variance states and different surface targets.

The JumpHMM advanced only on exchange sessions. We shifted every simulated growth-rate observation by a constant so the ensemble mean matched a prespecified annual growth prior. We then standardized the one-session simulated log returns across all paths and dates. The return shock used in the IV update was:

$$Z_{j,t}^S = \frac{\Delta \ln S_{j,t} - \bar{\Delta \ln S}}{s \Delta \ln S}. \quad (11)$$

An independent standard normal shock supplied the remaining variation. The coupled factor shock was:

$$Z_{j,t}^v = \rho Z_{j,t}^S + \sqrt{1 - \rho^2} Z_{j,t}^\perp, \quad Z_{j,t}^\perp \sim \mathcal{N}(0, 1). \quad (12)$$

The coefficient ρ was fixed at -0.6 . It was a return-shock coupling parameter, not a calibrated correlation between two Brownian motions in a standard Heston model.

We used a hard-floor Euler update with a trading-year step $\Delta t = 1/252$. The update was:

$$v_{a,t+1} = \max \left\{ v_{a,t} + \kappa(\bar{v}_{a,t} - v_{a,t})\Delta t + \sigma_v \sqrt{\max(v_{a,t}, 0)} \sqrt{\Delta t} Z_{j,t}^v, v_{\min} \right\}. \quad (13)$$

We fixed $\kappa = 15$, $\sigma_v = 0.5$, and $v_{\min} = (0.005)^2$. These values were scenario assumptions, not estimates from the option corpus. The floor protected the numerical pricer when the parameters did not satisfy the Feller condition Andersen [2008].

2.5 American-option pricing, calendar clock, and terminal profit and loss

Recombining lattices price American options by backward induction and compare continuation with immediate exercise at every node Broadie and Detemple [1996]. The Cox–Ross–Rubinstein construction uses up and down factors based on the supplied volatility Cox et al. [1979]. Jarrow–Rudd and Tian use alternative moment matches Jarrow and Rudd [1982], Tian [1993]. Leisen–Reimer uses a Peizer–Pratt inversion that places the strike more consistently in the tree and improves finite-step convergence Leisen and Reimer [1996]. Both pricers used here accepted one IV value for a given contract and date; they did not generate the IV surface themselves.

The GS and LLY contracts ran from April 28 to May 29, 2026. This interval contained 31 calendar days but 22 exchange-session transitions after excluding weekends and the May 25 market holiday. Calendar DTE entered the surface and lattice. JumpHMM and (13) advanced on the 22 trading transitions. For a date with τ_t calendar days remaining, the price input used $\tau_t/365$ years.

Corpus-wide dollar-price checks used a 200-step CRR American tree. Scenario marks and Greeks used a 201-step Leisen–Reimer American tree. Both stages used a constant risk-free rate of 4.25%

and continuous dividend yield $q = 0$. At expiration, the model replaced the lattice value with intrinsic value. For a short position that received market mid p_0 , terminal profit and loss was:

$$\Pi_T^{\text{put}} = p_0^{\text{put}} - \max(K - S_T, 0), \quad \Pi_T^{\text{call}} = p_0^{\text{call}} - \max(S_T - K, 0). \quad (14)$$

Equation (14) shows that terminal profit and loss depended on the JumpHMM terminal stock price, strike, and premium. Dynamic IV affected interim option marks and Greeks, but not a held-to-expiration payoff.

Greeks were calculated by central finite differences on the same Leisen-Reimer pricer. Spot bumps were $\pm 1.5\%$ of spot for delta and gamma. Volatility bumps were ± 0.005 , and Vega was reported per one volatility percentage point. We assumed execution at the observed mid, no transaction costs, no margin constraint, no early assignment before the plotted horizon, and no discrete dividends.

2.6 Inactive extensions

The repository also contains a proposed state-dependent level and aggregate tail-state mood multiplier. Those terms were held inactive in every experiment reported here. The present results evaluate the fitted level-times-surface model and the fixed return-shock coupling only. Testing state- and mood-dependent IV requires state-conditioned option histories and remains outside this study.

3 Results

We first report fitted and temporal-holdout IV errors, then use GS and LLY contracts to demonstrate the complete forward-simulation pipeline. The scenario results are fitted illustrations rather than additional validation experiments.

3.1 Cross-sectional IV-surface performance

We first asked whether added surface capacity and narrower parameter sharing reduced IV error. The corpus contained 234,549 observations for 31 tickers and fifteen capture dates from April 14 through May 11, 2026. We retained contracts with moneyness $K/S \in [0.80, 1.20]$, positive bids, positive DTE, and reported IV between 0.01 and 2.0. The six groups were technology, healthcare, financials, energy, retail, and broad-market exchange-traded funds. Supplementary Table S1 gives the ticker and observation counts.

We fitted three models with the common loss in (6): one global five-parameter shape, one global neural shape, and one neural shape per sector. All three used ticker-specific level parameters and differed only in shape capacity or sharing. On the pooled training corpus, RMSE fell from 12.48 to 11.47 volatility percentage points when the global neural surface replaced the parametric surface. Sector networks reduced it further to 10.24 points (Table 1). These changes corresponded to relative in-sample reductions of 8.1% and 17.9% from the parametric reference.

Table 1: In-sample IV RMSE on 234,549 observations. RMSE is reported in volatility percentage points. Each model fitted one ticker level jointly with its shape parameters.

Model	RMSE	Reduction from parametric
Parametric shape, global	12.48	reference
Neural shape, global	11.47	8.1%
Neural shape, six sectors	10.24	17.9%

The sector comparison showed where narrower sharing helped. Sector networks improved on the global network in all six groups, with the largest absolute reductions for exchange-traded funds and financials (Supplementary Table S2). Technology and healthcare retained the largest residual RMSE. Their worst-fitting tickers included QCOM, MU, INTC, AMD, PFE, and MRNA (Supplementary Table S3). This pattern showed that one surface per sector did not capture all within-sector variation. It did not identify a specific economic cause for each residual.

We also held out May 11, retrained on the other fourteen dates, and standardized inputs using training rows only. Pooled train RMSE was 10.21 points and test RMSE was 10.89 points, a 0.68-point

gap (Supplementary Table S4). Energy and retail had larger gaps than the other sectors. This single date and single training seed provide a limited temporal check. They do not establish generalization across market regimes or rule out overfitting.

3.2 Per-ticker neural surfaces

We next asked whether data-rich tickers benefited from their own shape. Twenty-nine of the 31 tickers exceeded 2,000 observations and received per-ticker networks; PFE and BMJ retained their sector networks. Tickers with at least 5,000 observations used the 337-parameter architecture, while the rest used 105 parameters. The combined model reduced pooled in-sample RMSE from 10.24 to 9.73 volatility percentage points and improved 21 of the 29 qualified tickers. JNJ, MRNA, AAPL, INTC, AMGN, MU, and NVDA had the largest reductions.

The representative panels show that the per-ticker curves followed local smile differences that were averaged away by the sector surfaces (Fig. 1). These are fitted comparisons on the same pooled corpus used for training. The separate ticker levels and network shapes should not be interpreted individually because the additive output bias and log level are not identified. The fitted IV product in (3), and its prediction error, are the meaningful quantities.

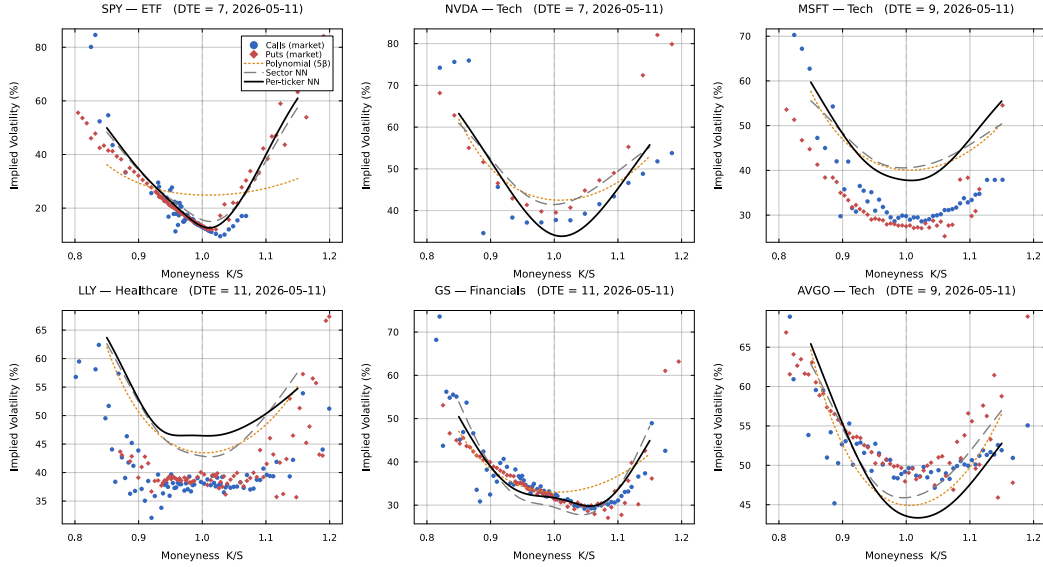

Figure 1: Fitted IV smiles for six representative tickers at a middle maturity. Points show market IV, the solid curve shows the per-ticker neural surface, and the dashed curve shows the sector surface. All observations came from the fifteen-date training corpus.

We translated IV errors into dollar-price errors on the May 11 capture using a 200-step CRR American tree (Fig. 2). The per-ticker model placed 33% of the plotted SPY contracts and 88% of the plotted GS contracts inside the local bid-ask half-spread band. On NVDA, all three surface tiers remained within about \$0.70. All model tiers overvalued the plotted LLY contracts by about \$2 to \$6, while the market-IV reference was near zero by construction. This comparison suggested that the LLY error arose mainly from a day-specific IV-level mismatch, not from the lattice implementation. The check still used the same date that contributed to the full-corpus surface fit, so it was descriptive rather than out of sample.

3.3 Temporal holdout with earnings inputs

A separate eight-day subset tested a fixed two-day temporal holdout. The training block contained six capture days from April 14 through April 22 and 103,897 rows. The April 23 and April 24 test block contained 26,833 rows. Every test ticker appeared during training. We compared a two-input pooled model (A), a two-input model after removing rows close to ticker or peer earnings dates from both splits (B), and a four-input earnings-aware model on the original rows (C).

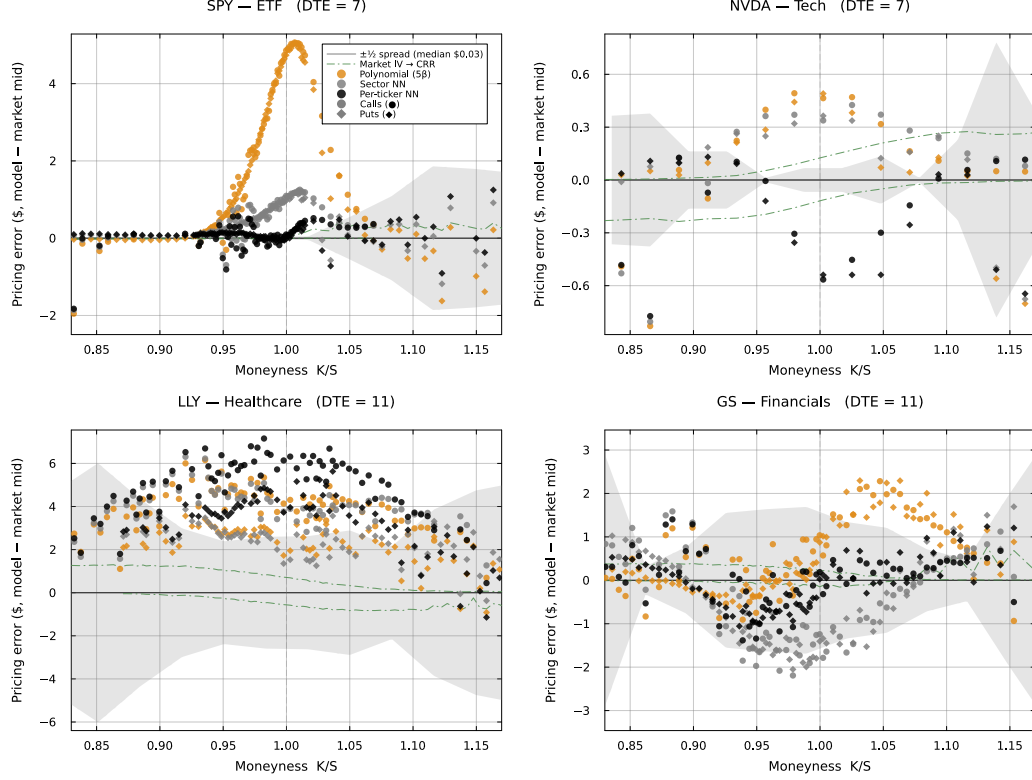

Figure 2: CRR American price minus market mid on May 11, 2026, for SPY, NVDA, LLY, and GS. Curves show the parametric, sector, per-ticker, and market-IV reference inputs. The gray ribbon is the median local bid-ask half-spread by moneyiness bin. A point inside the ribbon has an absolute pricing error below that local half-spread.

Table 2: Temporal-holdout comparison. RMSE and gaps are in volatility percentage points. Configuration B used different row sets from A and C.

Configuration	N_{tr}	N_{te}	Train RMSE	Test RMSE	Gap
A: pooled, two inputs	103,897	26,833	8.05	13.03	+4.99
B: non-earnings, two inputs	29,383	4,516	8.02	7.96	-0.06
C: earnings-aware, four inputs	103,897	26,833	7.61	11.98	+4.36

The earnings-aware model reduced test RMSE from 13.03 to 11.98 points, an absolute reduction of 1.05 points and a relative reduction of 8.1% (Table 2). Its train-to-test gap fell from 4.99 to 4.36 points, a 12.6% reduction. The largest ticker-level improvements occurred among technology names whose peers reported near the holdout dates (Supplementary Table S5). INTC error increased, which was consistent with a calendar feature being unable to encode the realized earnings surprise.

Configuration B had nearly equal train and test RMSE, but it removed most rows and changed the composition of both samples. It therefore did not show that earnings caused all of Configuration A's gap. It only showed that the retained non-event subset was easier under this split. More dates, repeated seeds, and matched-row comparisons are needed to separate event effects from changes in ticker and contract composition.

3.4 Forward-simulated fitted illustrations

The preceding results evaluate fitted IV surfaces and temporal prediction error. The following scenarios instead demonstrate how the fitted surface, JumpHMM paths, dynamic IV factors, and

American lattice interact. Because their surfaces used observations from the scenario period, these examples are not out-of-sample forecasts.

3.4.1 GS

We used observed GS contracts to illustrate the full simulation pipeline. The April 28, 2026, capture had spot $S_0 = \$926.38$. We selected the May 29 \$890 put with market delta -0.295 , mid \$16.51, and IV 31.3%, and the \$970 call with delta $+0.328$, mid \$16.09, and IV 28.9%. The fitted surface produced entry Leisen-Reimer values of \$17.26 and \$16.07 (Supplementary Table S6). The small entry differences show agreement with these two captured quotes, not out-of-sample pricing accuracy.

The maturity contained 31 calendar days and 22 trading transitions. We generated 1,000 JumpHMM paths and shifted their mean annual growth rate to a 10% scenario prior. The two contract factors used $\kappa = 15$, $\sigma_v = 0.5$, and $\rho = -0.6$. The lattice used a 4.25% risk-free rate, zero dividend yield, and 201 steps. These values were fixed scenario assumptions. The neural surface had been fitted on the full fifteen-date corpus, including April 28 and later dates, so this was a fitted illustration rather than a forecasting experiment.

Algorithm 1 states the operational sequence. Calendar DTE entered the surface and lattice, while the return generator and factor update advanced only on the exchange-session schedule. All stock paths were drawn before the return shocks were standardized across the ensemble.

Algorithm 1 Forward simulation of contract values

Require: JumpHMM marginal; fitted (θ_i, ψ_i) ; contract (K, T) ; trading dates $d_0, \dots, d_L$; calendar DTE $\tau_0, \dots, \tau_L$; (κ, σ_v, ρ) ; S_0 ; r ; N_p paths; LR depth N_{LR} .

Ensure: Stock, variance, IV, and option-value paths.

- 1: Draw N_p JumpHMM stock paths with L trading transitions.
 - 2: Compute $Z_{j,\ell}^S$ by standardizing all simulated one-session log returns as in (11).
 - 3: **for** contract a and path j **do**
 - 4: $v_{a,0}^{(j)} \leftarrow \theta_i \psi_i(\tau_0, K/S_0)$
 - 5: **for** $\ell = 0$ to $L-1$ **do**
 - 6: $\sigma_{a,\ell}^{(j)} \leftarrow \sqrt{v_{a,\ell}^{(j)}}$
 - 7: $P_{a,\ell}^{(j)} \leftarrow \text{LR}_{N_{LR}}(S_{j,\ell}, K, \sigma_{a,\ell}^{(j)}, \tau_\ell/365, r)$
 - 8: Draw $Z_{j,\ell}^\perp \sim \mathcal{N}(0, 1)$ and set $Z_{j,\ell}^v \leftarrow \rho Z_{j,\ell}^S + \sqrt{1 - \rho^2} Z_{j,\ell}^\perp$.
 - 9: $\bar{v}_{a,\ell}^{(j)} \leftarrow \theta_i \psi_i(\tau_\ell, K/S_{j,\ell})$
 - 10: Update $v_{a,\ell+1}^{(j)}$ with the hard-floor rule in (13) using $\Delta t = 1/252$.
 - 11: **end for**
 - 12: $P_{a,L}^{(j)} \leftarrow \max\{\phi(S_{j,L} - K), 0\}$, where $\phi = 1$ for a call and $\phi = -1$ for a put.
 - 13: **end for**
 - 14: **return** all paths.
-

The stock and option-value paths show the expected payoff geometry (Fig. 3). Low terminal-stock paths increased the put value, while high terminal-stock paths increased the call value. Interim option values also changed with remaining maturity and the contract-specific IV factors. The median option value fell to zero at expiration because more than half of the simulated terminal prices finished outside each strike.

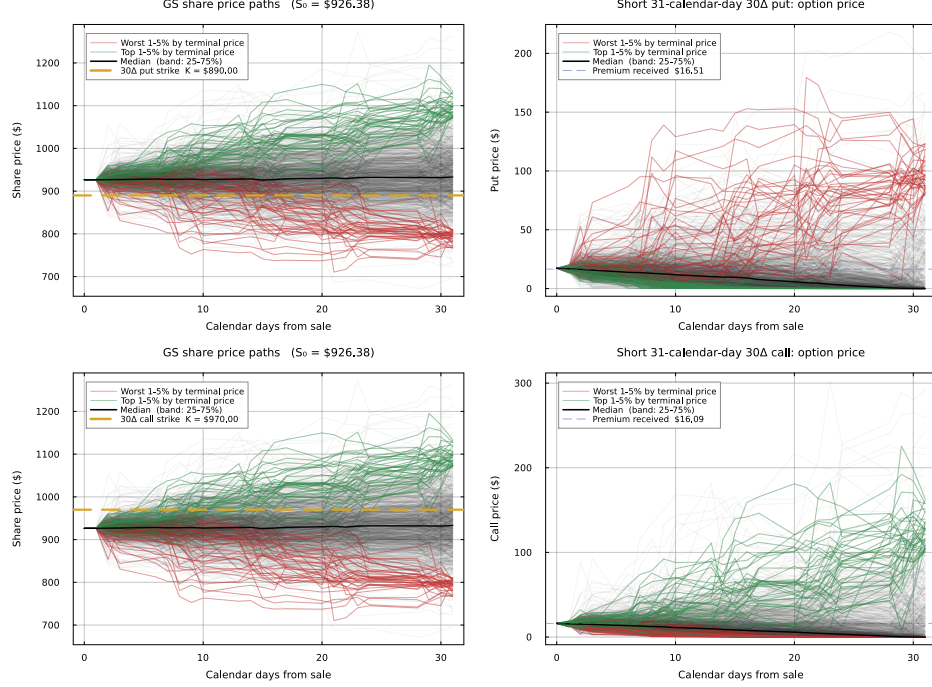

Figure 3: GS stock paths and long-option values for 1,000 trajectories from April 28 to May 29, 2026. The horizontal axis is calendar days, and the simulation contains 22 trading transitions. Red curves mark terminal-stock paths in the 1st through 5th percentiles; green curves mark the 95th through 99th percentiles. The blue horizontal lines show the market mids received by a short seller.

The IV panels answer a different question: how did the fitted surface and factor dynamics change interim marks? At the put and call strikes, IV varied with moneyness, calendar DTE, and the coupled factor shock (Fig. 4). Because $\rho = -0.6$, lower standardized stock returns tended to increase the factor shock. The figure illustrates that imposed dependence. It does not estimate a Heston leverage correlation or validate the IV paths against future quotes.

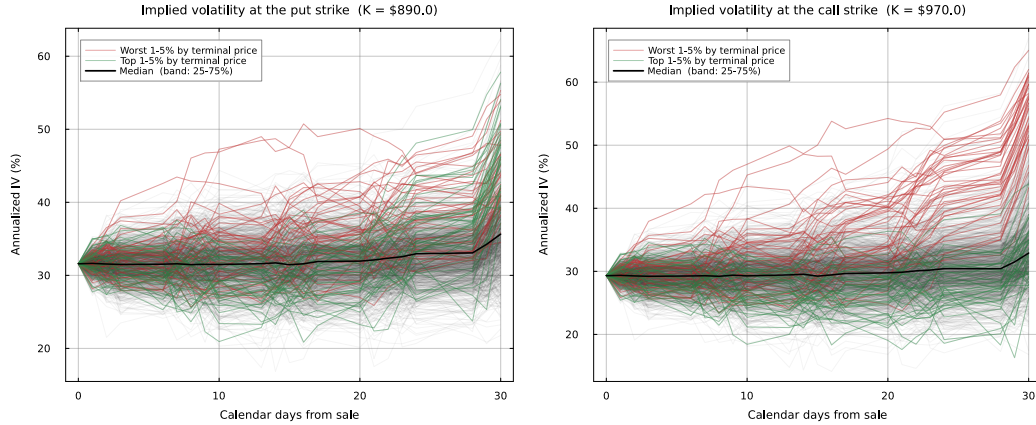

Figure 4: Contract-specific IV paths at the GS put strike (left) and call strike (right). The horizontal axis uses the 31-calendar-day schedule, with values updated on 22 trading transitions. Path colors follow Fig. 3.

The terminal P&L distributions had a mass at the premium ceiling and a left tail (Fig. 5). The put retained its full premium on 73.7% of paths, with a Wilson 95% interval of 70.9% to 76.3%. The call retained its premium on 68.8% of paths, with an interval of 65.9% to 71.6%. Put and call

mean P&L were +\$4.65 and −\$1.01. Their 5% quantiles were −\$59.61 and −\$83.67, while 5% expected shortfall was −\$90.73 and −\$125.62 (Supplementary Table S6). Expected shortfall is the mean P&L at or below the 5% quantile, so more negative values indicate a worse lower tail.

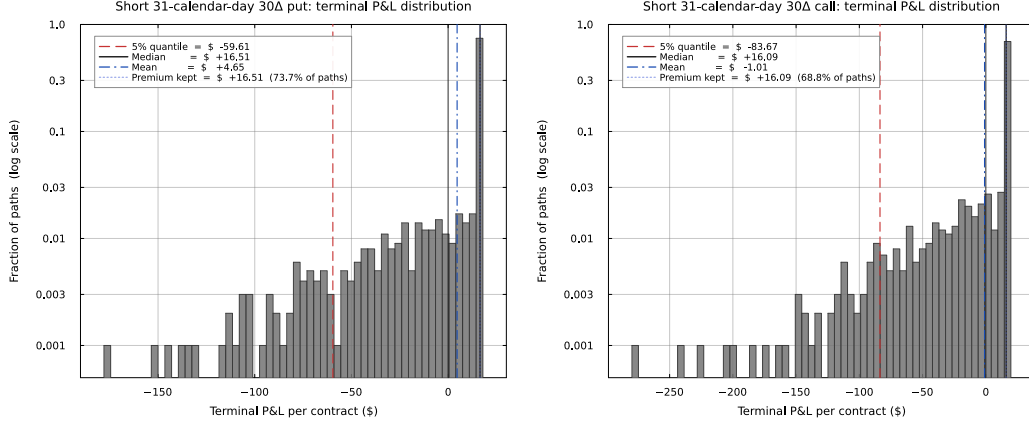

Figure 5: GS terminal short-option P&L per contract over 1,000 JumpHMM paths. The lattice IV process does not enter terminal P&L in (14); it affects only interim values and Greeks.

Market delta gave only a rough probability comparison. The heuristic $1 - |\Delta|$ predicted full-premium rates of 70.5% for the put and 67.2% for the call, versus simulated rates of 73.7% and 68.8%. The differences were 3.2 and 1.6 percentage points. This heuristic was not a validation target because market delta came from a risk-neutral quote convention, whereas strike-crossing frequencies came from the drift-adjusted physical JumpHMM paths.

The finite-difference Greeks described how interim exposure changed. Delta approached its terminal exercise values, gamma concentrated near the strike, and Vega declined as calendar DTE approached zero (Supplementary Fig. S1). These results follow from the option payoff and lattice calculations conditional on the simulated (S_t, σ_t) pairs. Short-position Greeks are the negatives of the displayed long-option Greeks.

3.4.2 LLY

We repeated the same calculation for LLY to check whether the software path ran under a different return marginal and IV level. The April 28 capture had spot \$873.83. The May 29 \$825 put had delta −0.303, mid \$23.30, and IV 44.4%; the \$940 call had delta +0.309, mid \$20.76, and IV 44.0%. The fitted entry values were \$21.95 and \$18.96. All simulation settings, including the 31-calendar-day and 22-transition clock, matched the GS case.

The LLY terminal distributions also had a premium ceiling and left tail (Fig. 6). The put retained its premium on 81.2% of paths (Wilson 95% interval 78.7% to 83.5%), and the call did so on 80.3% (77.7% to 82.6%). Mean P&L was +\$16.69 for the put and +\$11.42 for the call. Their 5% quantiles were −\$22.12 and −\$47.31, and expected shortfall was −\$51.43 and −\$89.21 (Supplementary Table S7). The delta heuristic predicted 69.7% and 69.1%, well below both simulated rates. This gap further illustrates why market delta should not be read as a calibrated physical strike-crossing probability in these scenarios.

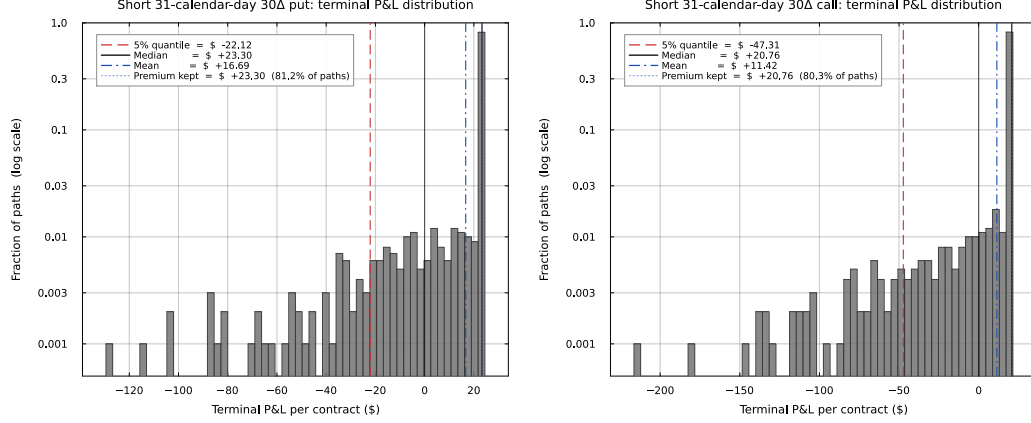

Figure 6: LLY terminal short-option P&L per contract over 1,000 JumpHMM paths. The wider lower tail for the call came from the simulated terminal-stock distribution relative to the call strike and entry premium.

The LLY result was a second fitted illustration, not cross-ticker validation in a statistical sense. It used one seed, one maturity window, fixed factor parameters, and a neural surface fitted with observations from the same period. Supplementary Figs. S2–S4 report its stock, option-value, IV, and Greek paths.

4 Discussion

The study supports a modular synthetic-option workflow. Offline market IV calibration supplied a positive surface, JumpHMM supplied non-Gaussian stock paths, contract-specific square-root factors supplied dynamic lattice IV, and American lattices supplied prices and Greeks. This organization removed the need for a contemporaneous option quote at each simulated step. It did not remove the need for historical option data, and it did not produce IV from equity returns alone. The fitted IV surface remained an empirical input learned from option ladders.

The calibration comparisons showed two useful patterns. First, replacing the five-parameter global surface with a neural surface reduced pooled in-sample error. Second, sector sharing improved further on the global network, while per-ticker fits helped many data-rich names. These comparisons concern the fitted product $\theta_i \psi_i$. The level and neural shape are not separately identified because the network output contains an additive bias. A normalization constraint would be required before comparing estimated levels across tickers or assigning economic meaning to either component.

The temporal checks were informative but narrow. On the May 11 holdout, pooled test RMSE exceeded train RMSE by 0.68 volatility percentage points. On the April 23 and April 24 holdout, earnings inputs reduced test RMSE by 1.05 points. Removing event-adjacent rows produced a much easier subset, but it also changed most of the training and test observations. The exclusion therefore cannot identify earnings as the cause of the full generalization gap. Repeated date blocks, matched samples, and multiple training seeds would provide a stronger test.

The scenario results separate interim valuation from terminal payoff risk. The dynamic IV factors changed option marks and Greeks before expiration. Once the contracts reached expiration, Equation (14) depended only on the JumpHMM terminal stock price, strike, and collected premium. The call-versus-put tail differences in Figs. 5 and 6 therefore describe the fitted JumpHMM marginals relative to the selected contracts. They are not evidence that the neural IV skew or factor coupling caused terminal P&L asymmetry.

Several extensions could address the present scope. Static no-arbitrage penalties could impose strike convexity and calendar consistency during surface training. A normalization such as zero mean log shape on a reference grid could identify the ticker level relative to shape. State-conditioned option histories could test the proposed JumpHMM-state and aggregate-mood terms that remained inactive here. Finally, repeated rolling-origin experiments could evaluate day-specific adaptation, including earnings events and unscheduled volatility shifts, without training on the scenario date.

The study has important limitations. The surface networks enforced positivity but not static arbitrage. The GS and LLY examples used only 1,000 paths, one random seed, two tickers, one maturity window, and fixed κ , σ_v , and ρ values that were not calibrated. Both surfaces used the full corpus, so neither example was out of sample. The pricing assumptions set dividend yield to zero and omitted discrete dividends, transaction costs, bid-ask execution, margin, and early assignment. The held-to-expiration P&L analysis did not test hedging or mark-to-market liquidation. The state and mood mechanisms were inactive, and the model was not a standard Heston joint stock-variance process. These restrictions limit the results to a software and modeling illustration rather than a validated trading or risk system.

5 Conclusion

We developed a synthetic American-option pipeline that combined JumpHMM stock paths, fitted IV surfaces, contract-specific square-root IV factors, and recombining lattices. Neural and sector-specific surfaces reduced in-sample IV error relative to a global five-parameter surface, and the tested earnings inputs reduced error on one two-day temporal holdout. These results support the modular representation, while the limited splits do not establish broad temporal generalization.

The GS and LLY examples produced stock, IV, option-value, and Greek paths under an explicit 31-calendar-day and 22-transition schedule. They also clarified the source of terminal risk: IV dynamics affected interim marks and Greeks, while held-to-expiration P&L depended on the JumpHMM terminal stock price and payoff. The open-source repository provides a basis for stronger rolling-origin validation, arbitrage-constrained surfaces, calibrated factor dynamics, and scenarios that include dividends and trading frictions.

A Interpretation of the Contract Variance Factor

The scenario model assigned a variance state to each contract rather than one instantaneous variance state to the underlying. For a fixed target, the continuous-time process motivating the Euler update is:

$$dv_{a,t} = \kappa(\bar{v}_{a,t} - v_{a,t}) dt + \sigma_v \sqrt{v_{a,t}} dW_{a,t}. \quad (15)$$

Contract a indexes ticker, strike, and expiration. The target $\bar{v}_{a,t}$ in (8) changes with current money-ness and calendar DTE. If that target were held fixed and a stationary distribution existed, its mean would equal $\bar{v}_a$. In the implemented scenario, however, the target moved at every trading date and the hard floor in (13) altered the unconstrained square-root process. We therefore use the stationary result only as motivation for mean reversion, not as a claim about the simulated distribution.

At entry, $v_{a,0} = \bar{v}_{a,0}$ reproduces the fitted IV product exactly. Thereafter, $\sigma_{a,t}^2 = v_{a,t}$ supplies the lattice input. The fitted level and neural shape are not separately identified: shifting a constant between $\ln \theta_i$ and the network output bias leaves $\theta_i \psi_i$ unchanged. This does not change fitted IV or scenario output, but it prevents separate economic interpretation of the two components.

B Calibration Details

Table S1 reports the corpus composition. Tables S2 and S3 report sector and ticker errors for the three pooled calibration tiers.

Table S1: Sector partition of the 31-ticker ladder across fifteen capture dates. Counts are filtered observations used in calibration.

Sector	Observations	Tickers
ETF	102,738	IWM, QQQ, SPY
Technology	68,334	AAPL, AMD, AVGO, GOOG, INTC, META, MSFT, MU, NVDA, QCOM
Healthcare	26,387	ABBV, AMGN, BMY, JNJ, LLY, MRNA, PFE, UNH
Financials	17,938	BAC, GS, JPM, WFC
Retail	11,320	TGT, UPS, WMT
Energy	7,832	CVX, OXY, XOM

Table S2: In-sample RMSE by sector, in volatility percentage points. The sector network improved on the global neural network in every group, while technology and healthcare retained the largest errors.

Sector	Parametric	Global NN	Sector NN	Observations
ETF	10.54	8.69	6.10	102,738
Financials	9.05	7.79	6.70	17,938
Energy	9.36	8.24	7.88	7,832
Retail	11.73	10.23	9.50	11,320
Healthcare	13.49	12.71	12.53	26,387
Technology	15.58	15.31	14.47	68,334

B.1 Single-date holdout

We held out May 11, 2026, and retrained on the other fourteen dates. The holdout had 14,442 observations. Standardization used training rows only. Table S4 shows that pooled test RMSE exceeded train RMSE by 0.68 volatility percentage points, with larger gaps in energy and retail. Because this analysis used one date and one seed, it is evidence for that split only.

C Earnings-Holdout Ticker Results

The technology-ticker breakdown showed where the four-input model changed holdout error (Table S5). Several tickers with a peer earnings date near the holdout improved, while INTC and NVDA

Table S3: Best and worst ticker-level in-sample RMSE under the sector networks. RMSE is in volatility percentage points.

Rank	Ticker	Observations	RMSE	Sector
<i>Best five</i>				
1	GS	8,772	5.40	Financials
2	SPY	42,224	6.02	ETF
3	IWM	21,368	6.11	ETF
4	QQQ	39,146	6.17	ETF
5	JPM	3,720	6.18	Financials
<i>Worst five</i>				
27	PFE	1,300	17.66	Healthcare
28	AMD	4,566	17.74	Technology
29	INTC	3,417	17.78	Technology
30	MU	6,619	18.45	Technology
31	QCOM	3,375	21.46	Technology

Table S4: Sector-network RMSE for the May 11 single-date holdout. Values and test-minus-train gaps are in volatility percentage points.

Sector	Train	Test	Gap
ETF	6.12	5.87	−0.25
Financials	6.72	6.32	−0.40
Healthcare	12.58	12.00	−0.58
Technology	14.45	15.04	+0.58
Energy	7.74	9.97	+2.23
Retail	9.21	13.17	+3.96
Pooled	10.21	10.89	+0.68

worsened. This pattern was consistent with a peer-calendar signal, but the shared training process did not isolate the marginal effect of either event input.

Table S5: Technology-ticker test RMSE for the pooled model (A) and earnings-aware model (C). Inputs e and e^{peer} are median signed ticker distance and minimum peer distance, in days. RMSE differences are in volatility percentage points.

Ticker	e	e^{peer}	A: pooled	C: event inputs	Difference
QCOM	+5	1	41.66	37.59	−4.07
AMD	+11	1	40.07	36.50	−3.57
META	+5	1	14.32	10.73	−3.59
MSFT	+5	1	14.00	10.73	−3.28
GOOG	+5	1	9.87	7.90	−1.97
MU	−30	1	16.95	15.59	−1.36
AAPL	+6	1	10.42	10.34	−0.08
AVGO	+30	1	12.58	12.83	+0.24
NVDA	+26	1	9.43	10.47	+1.05
INTC	−1	5	33.17	35.94	+2.77

D Scenario Statistics and Greeks

Table S6 reports the GS terminal distribution. The 5% expected shortfall is the mean P&L among observations at or below the empirical 5% quantile. The premium-retained interval is a two-sided 95% Wilson interval for the binomial fraction of paths that expired out of the money.

Table S6: GS results from 1,000 paths between April 28 and May 29, 2026. The horizon had 31 calendar days and 22 trading transitions. Dollar values are per contract.

Statistic	Short put	Short call
Strike	\$890	\$970
Market mid	+\$16.51	+\$16.09
Model entry value	\$17.26	\$16.07
Model value minus market mid	+\$0.75	−\$0.02
Mean P&L	+\$4.65	−\$1.01
Monte Carlo SE of mean	\$0.87	\$1.18
Median P&L	+\$16.51	+\$16.09
Standard deviation	\$27.44	\$37.17
5% quantile	−\$59.61	−\$83.67
5% expected shortfall	−\$90.73	−\$125.62
Premium retained	73.7%	68.8%
Wilson 95% interval	70.9–76.3%	65.9–71.6%

The Greek calculation used the same Leisen-Reimer price function as the base mark. The finite-difference calculation was:

Algorithm 2 Path-conditional Greeks by central finite differences

Require: State (S, σ, τ) ; contract (K, r) ; LR depth N_{LR} ; relative spot bump h_S ; absolute IV bump h_σ .

Ensure: Δ , Γ , and Vega.

- 1: $P_+^S \leftarrow \text{LR}(S(1 + h_S), K, \sigma, \tau, r)$ and $P_-^S \leftarrow \text{LR}(S(1 - h_S), K, \sigma, \tau, r)$.
 - 2: $P_0 \leftarrow \text{LR}(S, K, \sigma, \tau, r)$.
 - 3: $P_+^\sigma \leftarrow \text{LR}(S, K, \sigma + h_\sigma, \tau, r)$ and $P_-^\sigma \leftarrow \text{LR}(S, K, \sigma - h_\sigma, \tau, r)$.
 - 4: $\Delta \leftarrow (P_+^S - P_-^S)/(2h_S S)$.
 - 5: $\Gamma \leftarrow (P_+^S - 2P_0 + P_-^S)/(h_S S)^2$.
 - 6: $\text{Vega} \leftarrow 0.01(P_+^\sigma - P_-^\sigma)/(2h_\sigma)$.
 - 7: **return** $(\Delta, \Gamma, \text{Vega})$.
-

The GS Greek paths from Algorithm 2 are shown in Fig. S1. Delta approached the terminal exercise states, gamma was largest near the strike late in the horizon, and Vega declined toward zero. The displayed values use the long-option convention.

The corresponding LLY terminal results are reported in Table S7. The scenario used the same clock, path count, seed, lattice settings, and factor parameters as GS.

Figures S2–S4 show the LLY path outputs. They use the same plotting conventions as the GS figures.

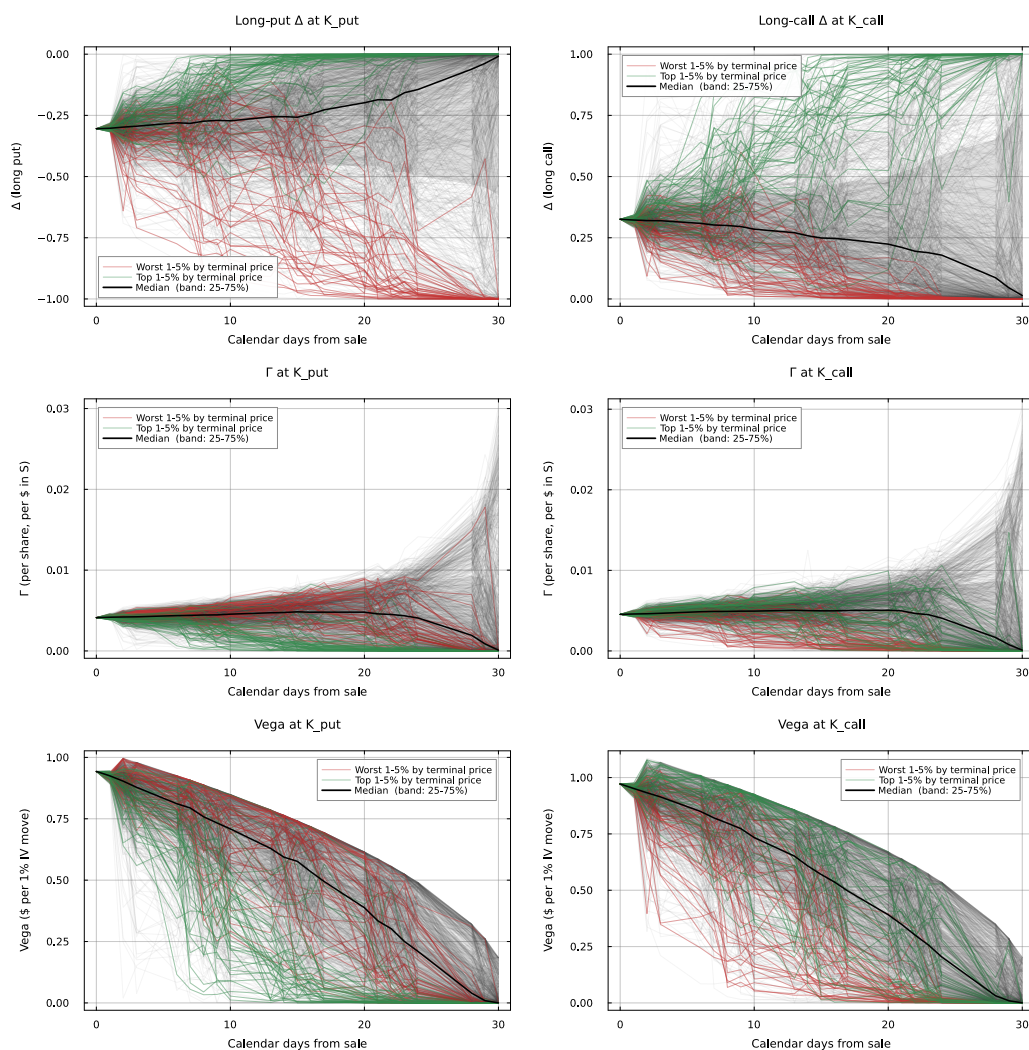

Figure S1: GS long-option delta, gamma, and Vega from the 201-step Leisen-Reimer pricer. Spot bumps were 1.5% of spot, and IV bumps were 0.005. Vega is dollars per one volatility percentage point.

Table S7: LLY results from 1,000 paths between April 28 and May 29, 2026. The horizon had 31 calendar days and 22 trading transitions. Dollar values are per contract.

Statistic	Short put	Short call
Strike	\$825	\$940
Market mid	+\$23.30	+\$20.76
Model entry value	\$21.95	\$18.96
Model value minus market mid	-\$1.35	-\$1.80
Mean P&L	+\$16.69	+\$11.42
Monte Carlo SE of mean	\$0.59	\$0.86
Median P&L	+\$23.30	+\$20.76
Standard deviation	\$18.78	\$27.10
5% quantile	-\$22.12	-\$47.31
5% expected shortfall	-\$51.43	-\$89.21
Premium retained	81.2%	80.3%
Wilson 95% interval	78.7–83.5%	77.7–82.6%

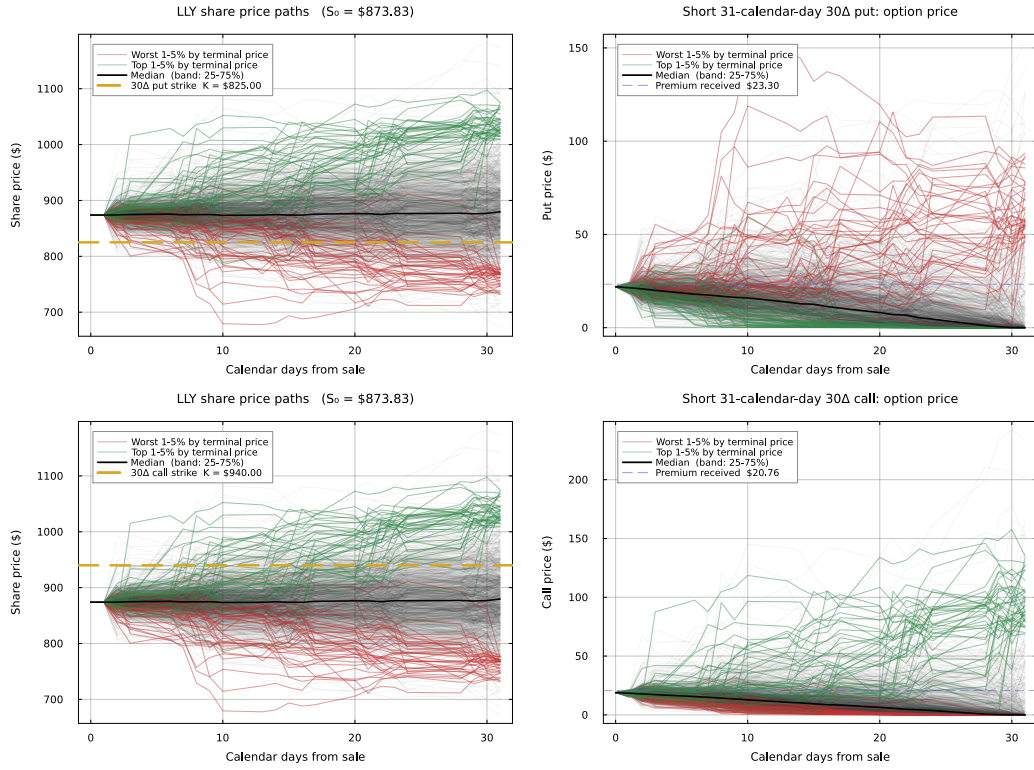

Figure S2: LLY stock paths and long-option values across 31 calendar days and 22 trading transitions. Red and green overlays identify the 1st through 5th and 95th through 99th terminal-stock percentiles.

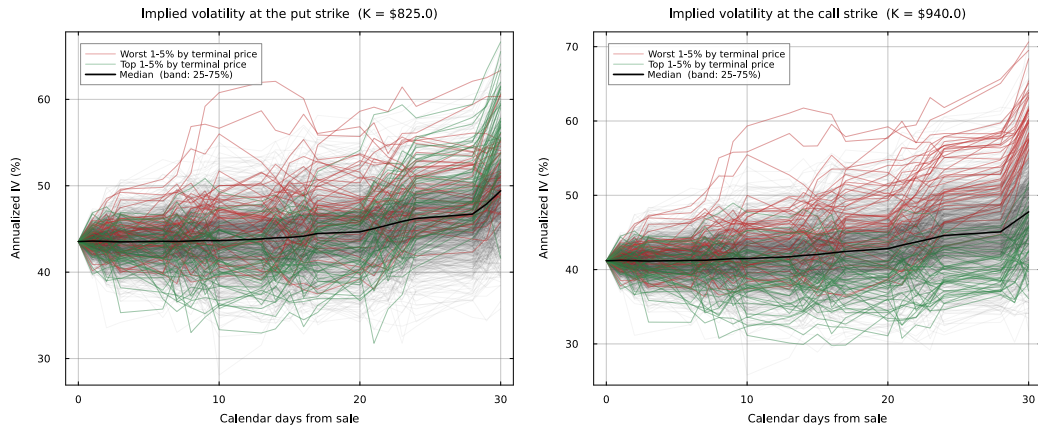

Figure S3: Contract-specific LLY IV paths at the put and call strikes. The fixed negative return-shock coupling tended to raise factor shocks after lower standardized returns.

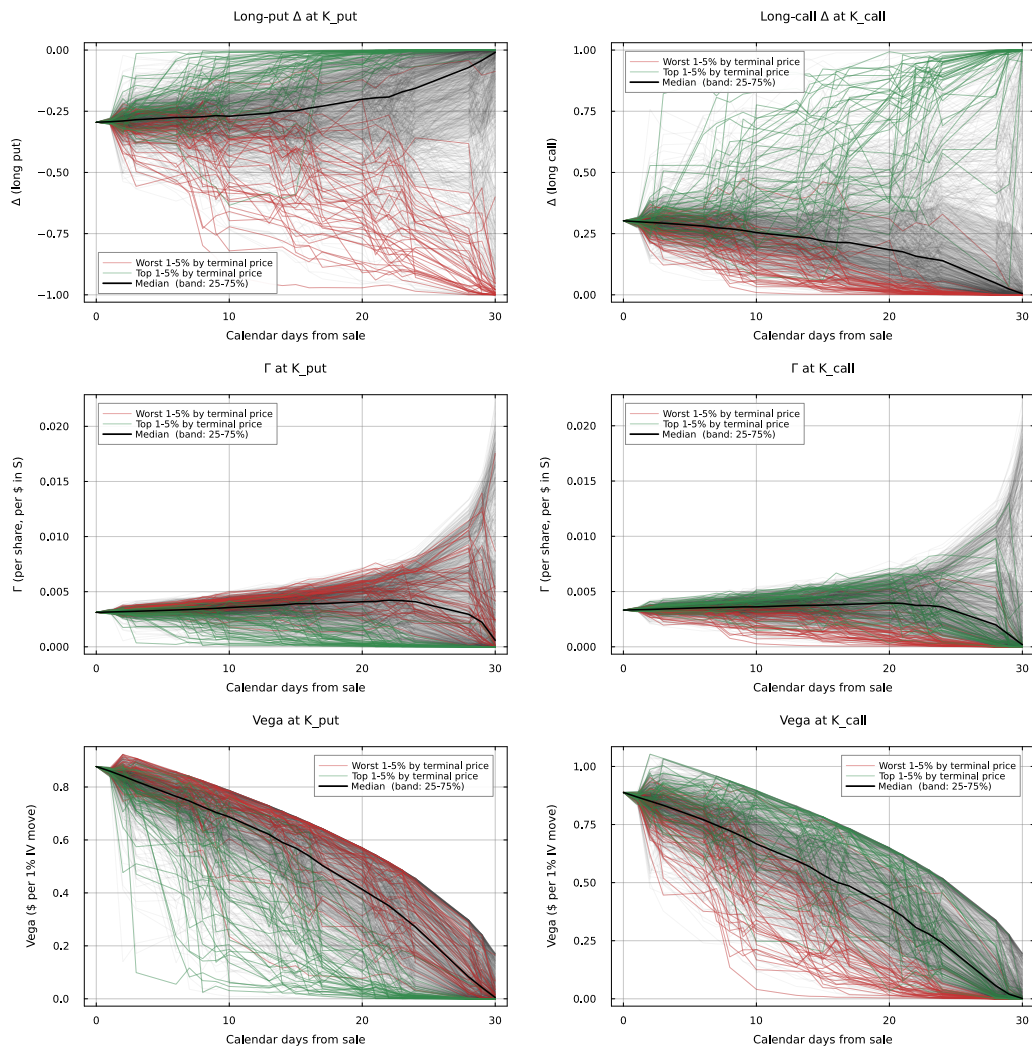

Figure S4: LLY long-option delta, gamma, and Vega from the 201-step Leisen-Reimer pricer. Short-position Greeks have the opposite sign.
