Abstract

Valuing American options along simulated stock paths requires an implied volatility (IV) for every option on every date. A stock-return model alone does not provide it. In this study, we built a simulator that assigned IV to American options on simulated dates for any chosen stock model. We fitted parametric and neural IV surfaces to vendor option quotes for 31 tickers. Each surface predicted IV from moneyness and time to expiration. Stock paths came from a jump hidden Markov model with capped daily returns. Each day, every option's implied variance moved partway toward its surface prediction, following the form of the Heston variance equation. Random shocks tended to raise IV when the stock fell. A binomial tree converted IV into option values and price sensitivities. Neural surfaces fitted by sector or ticker matched the quotes more closely than one parametric surface. Their errors still varied by date and carried into dollar prices. Repricing identical stock paths under five ways of updating IV changed option values before expiration and the worst losses from closing short positions early. Payoffs at expiration did not change. In forecasts of later Goldman Sachs and Eli Lilly option prices, stochastic IV did little better than fixed IV. Rerunning the forecasts with the realized stock paths showed that stock-forecast errors caused most misses. The hidden Markov model, an adaptive-volatility model, and a direction-predicting model all predicted stock prices about as accurately as assuming no change. The adaptive-volatility model improved predicted price ranges for Eli Lilly but not Goldman Sachs. The simulator supported reproducible comparisons of IV and stock assumptions but did not forecast better than simpler alternatives. Complete option histories and prices consistent across strikes are needed before simulated prices can replace market data.

1 Introduction

Implied volatility (IV) is the volatility that makes a pricing model, such as that of Black and Scholes [Black and Scholes \[1973\]](#), reproduce an observed option price [Latané and Rendleman \[1976\]](#). An option's IV is therefore backed out of its market price rather than observed on its own. A simulated stock path has no option prices, so it has no IV either. Without an IV, a pricing model cannot value an option on a simulated date. A stock portfolio can be stress-tested or backtested on simulated price paths directly, because each simulated price is the position's value. An option position cannot, because its value on each simulated date also depends on an IV that the simulation does not supply. Those dates matter. Option strategies are judged by their payoffs at expiration but managed on every date before it. A short put that expires worthless can still lose money if the stock falls first and the trader has to close or hedge the position. American options make the earlier dates matter

even more, since the holder may exercise on any of them. A simulation that values options along stock paths therefore needs two parts. The first is a stock model that reproduces the return behavior the stress test or backtest depends on, such as heavy tails and volatility clustering [Cont \[2001\]](#). The second is a rule that assigns every option an IV across strikes and expiration dates and updates it as the simulated stock moves.

Existing approaches address different parts of this problem through their choices of return dynamics, volatility representation, and pricing model. Parametric models such as stochastic alpha beta rho (SABR) and stochastic volatility inspired (SVI) provide compact descriptions of volatility smiles [Hagan et al. \[2002\]](#), [Gatheral \[2004\]](#). Neural networks can learn the pricing map of a specified volatility model, which speeds up its pricing and calibration [Horvath et al. \[2021\]](#), [Bayer and Stemper \[2018\]](#). Models of IV-surface dynamics describe changes in level, skew, and curvature through common factors [Cont and da Fonseca \[2002\]](#), with more recent methods incorporating static arbitrage constraints into surface simulation [Cont and Vuletić \[2023\]](#). Local- and stochastic-volatility models instead place stock and volatility dynamics within a joint pricing model [Dupire \[1994\]](#), [Derman and Kani \[1994\]](#), [Heston \[1993\]](#). Each of these can price options at strikes, expiration dates, or market states that were never quoted. Most, however, either describe the smile on a single date or bring stock dynamics of their own. They are not built to take stock paths from a separately chosen generator as given. That limitation matters when a researcher has already chosen a stock-return generator for how well it matches real returns and wants to vary only the volatility assumptions. Synthetic return generators, from regime-switching models with jumps to generative neural networks, can reproduce important features of equity returns [Cont \[2001\]](#), [Wiese et al. \[2020\]](#), [Alswaidan and Varner \[2026\]](#). Their paths carry no option prices. What is missing is a rule that takes each simulated stock path as given and assigns every option an IV along it. Such a rule would let researchers compare volatility assumptions on identical stock paths. It would be useful only if the resulting prices matched market quotes and stayed free of arbitrage across strikes and expiration dates.

In this study, we built a simulator that takes stock paths from any synthetic generator and assigns every American option an IV along them. Each day, the simulator moves every option’s IV partway toward a target read from an IV surface fitted to market quotes and adds random shocks partly tied to the stock’s moves. A binomial tree then converts that IV into the option’s price [Cox et al. \[1979\]](#), [Leisen and Reimer \[1996\]](#). We used the simulator to ask three questions. The first was whether fitted surfaces were accurate enough to serve as these targets. They served that role only in part. Surfaces fitted separately to sectors or single stocks matched the quotes better than one surface for all stocks, but their accuracy on later dates was uneven. The second was whether the way IV was updated mattered when the stock paths were held fixed. It did. Updates ranging from fixed IV to the full update with random shocks gave different option values before expiration and different worst losses from closing short positions early. An analysis of payoffs at expiration alone would miss these differences. The third was whether the simulator could forecast later option prices. With the full IV update, it forecast them only slightly better than with IV held fixed, and most of the error came from the stock forecast, which no IV update can correct. Some simulated prices were also inconsistent across strikes, and consistency across expiration dates was not tested. The simulator is therefore better suited to controlled comparisons of volatility assumptions than to forecasting or to replacing market data. More broadly, the approach turns any synthetic stock generator into a source of option scenarios for stress tests and backtests on hypothetical market paths.

2 Methods

2.1 Simulator overview and stock paths

The simulator values options along simulated stock paths in two phases. In the first phase, before any simulation, we fitted IV surfaces to observed option quotes. Each surface predicts an option’s IV from its moneyness (strike divided by stock price) and its time to expiration. In the second phase, the simulator generates complete stock paths and then moves forward along each path one trading day at a time, using the fitted surfaces and, apart from the starting IVs in the forecast test, no further option quotes. On each day, a binomial tree prices each option from the current stock price, the remaining time to expiration, and the option’s current IV. The same tree supplies the option’s price sensitivities (Greeks). The option’s implied variance, the square of its IV, then moves partway toward the variance that the surface predicts for its current moneyness and remaining time. The

move also carries random shocks partly tied to the stock’s return. Option prices never feed back into the surfaces or the stock paths, so information flows in one direction, from the stock price to IV to the option price (Algorithm 1).

We used the fitted surfaces and the simulator in five analyses. First, we measured how closely the surfaces matched the quotes they were fitted to, in IV and in dollar prices, and how well they transferred to dates withheld from fitting. Second, we simulated short positions in one put and one call on Goldman Sachs (GS) and on Eli Lilly (LLY), opened on April 28, 2026, as illustrations. Third, we repriced these options on new simulated paths under five ways of setting IV: holding it fixed, setting it each day to the surface’s prediction, and three versions of the daily update described below. All five shared the same stock paths, so their differences isolate the effect of each rule, and we call this paired comparison the IV ablation. Fourth, we tested the surfaces and the simulator on dates after the calibration window, which ended on May 11, including a forecast test of GS and LLY option prices issued daily in August and early September. Fifth, we compared the stock forecasts of JumpHMM, the stock model described next, with those of simpler stock models.

The stock paths came from the Jump Hidden Markov Model (JumpHMM) [Alswaidan and Varner \[2026\]](#). We used the per-ticker models fitted in the study that introduced JumpHMM, which fitted 424 tickers separately, each on 2,767 trading days of prices from 2014 to 2024. Each model describes a ticker’s excess growth rate, its annualized log return minus a risk-free rate, with 50 hidden states. Each state draws the growth rate from its own location-scale Student- t distribution, called the state’s emission distribution. The tail states are the few states at each end of the growth-rate range, which produce extreme growth rates. A jump mechanism occasionally forces the model into a tail state and keeps it there for a run of consecutive days, called a jump episode, whose length follows a Poisson distribution. The original study tuned how often episodes start and how long they last. In the original study, the model reproduced heavy tails and part of the volatility clustering of equity returns [Alswaidan and Varner \[2026\]](#), two features documented across many markets [Cont \[2001\]](#). The models used a time step of $1/252$ year and a risk-free rate of zero, so each growth rate is simply an annualized log return. Through a Student- t copula [Demarta and McNeil \[2005\]](#), JumpHMM can link several tickers, but every simulation here used one ticker at a time.

For price simulation, we cut off each Student- t emission distribution at a finite bound. Without a cutoff, exponentiating Student- t log returns gives an infinite expected stock price, so mean call values and expected short-call losses would have no finite population value [Cassidy et al. \[2010\]](#). The simulated growth rate on day t was given by:

$$G_t = \mu_{k_t} + \sigma_{k_t} Z_t, \quad Z_t \sim t_{\nu_{k_t}} \mid |Z_t| \leq b, \quad b = 10, \quad (1)$$

where k_t is the hidden state on day t , μ_k and σ_k are the fitted location and scale of state k , ν_k is its degrees of freedom, and Z_t is a Student- t draw restricted to $|Z_t| \leq b$. The cutoff b is therefore measured in multiples of the state’s scale. We redrew any value outside the bound, so no stock path was discarded. The cutoff kept the states and the jump mechanism intact and gave the stock price a finite mean and variance at every horizon. We applied it only in simulation, and the locations, scales, transition matrix, and jump parameters kept their fitted values. Each simulated price then followed from $S_{t+1} = S_t \exp[(G_t + c)\Delta t]$ with $\Delta t = 1/252$, where the growth shift c is a constant added to every growth rate. We set c separately for each ticker so that the mean simulated growth rate, an annualized log return, equaled 10% a year. The illustrations estimated c from their own simulated paths. The IV ablation and the forecast test instead estimated it from a separate pilot simulation and then drew fresh paths for scoring, which we call evaluation paths, so the scored paths never influenced c . Without this shift, the fitted models would carry the average drift of their 2014–2024 fitting period into every simulation. We set the cutoff $b = 10$, and a wider $b = 20$ for a sensitivity check, in advance as stress assumptions rather than by forecast performance. The sensitivity reruns repeated each analysis with the same options, seeds, and dates. For $b = 20$, they recomputed the growth shift and the other constants estimated from simulated returns (Supplementary Tables [S33](#), [S34](#), and [S35](#)).

2.2 Option data and IV surfaces

We downloaded option data from Alpaca Markets with a free account, which supplies Alpaca’s indicative feed. Alpaca derives this feed from the consolidated exchange feed of the Options Price Reporting Authority (OPRA), but its quotes are indicative rather than actual exchange quotes [Alpaca Markets \[2026b\]](#). Every quote, midpoint, spread, and reported IV in this study is therefore an Alpaca

value, which may differ from exchange quotes and from prices at which trades could execute. After each trading session, a download script saved one file per ticker with the session’s closing stock price and the quoted calls and puts. Each file kept only the expirations nearest a fixed ladder of target maturities, 2, 7, 14, 30, and 45 calendar days, with 60 and 90 days added on some dates. The data therefore covered many strikes but only a few expirations per ticker and day. The fitting target was the IV that Alpaca reports with each quote. Alpaca computes this IV with the Black–Scholes formula, solved iteratively using the price sensitivity to volatility (Vega) [Alpaca Markets \[2026a\]](#). Because that formula prices European options, an American tree given this IV need not reproduce the quoted price exactly.

Each daily download is a snapshot. It has three dates, the label of its data folder, the date the files were downloaded, and the session whose closing price they store. These usually agree but not always (Supplementary Table S1). Some downloads ran after midnight UTC, so the snapshot labeled April 14 stores the April 13 close, and one folder, labeled April 29, holds a download of the April 30 close. For the dates used most below, April 28 and May 11, the label and the session agree. The calibration data set used the first fifteen snapshots, labeled April 14 through May 11, 2026. Not every trading day in that span was captured. It contained 457 ticker files, because the first snapshot covered 23 tickers and each later snapshot covered 31. The 31 tickers were 28 stocks and three exchange-traded funds (ETFs). After filtering, 234,549 observations remained. The filters kept calls and puts with a positive bid, positive calendar days to expiration (DTE), reported IV strictly between 0.01 and 2.0, and moneyness K/S between 0.8 and 1.2 inclusive, with S the stored closing stock price. The calibration fits used the DTE stored in each file, which in two snapshots, labeled April 23 and May 1, counted from the download date rather than the session date. Calls and puts entered the same fitting loss, and an option that appeared in several snapshots counted once per snapshot. The download script continued daily through September 4, 2026. We used these later files to refit sector networks on data through July 31 and to score surfaces on later dates.

We compared four ways of sharing surfaces across tickers: one parametric surface for all tickers, one neural surface for all tickers, one neural surface per sector, and neural surfaces for single tickers. The six sectors group the 31 tickers by industry, with the three ETFs as a sector of their own (Supplementary Table S2). Every surface predicts squared IV as a ticker level multiplied by a shape function of maturity and moneyness. Each shape is the exponential of a polynomial or of a network output, which keeps it positive. Two conditions rule out simple arbitrage. Calendar monotonicity requires total implied variance, squared IV times time to expiration, never to fall as maturity lengthens at fixed moneyness. Strike convexity requires option prices to be convex in strike. We imposed neither condition during fitting, so the fitted surfaces needed separate no-arbitrage checks. The parametric shape follows the compact tradition of SABR and SVI [Hagan et al. \[2002\]](#), [Gatheral \[2004\]](#), and all tickers shared its coefficients. It was given by:

$$\psi_\beta(\tau, m) = \exp[\beta_1 \ln \tau + \beta_2 \ln m + \beta_3 \ln \tau \ln m + \beta_4 (\ln m)^2 + \beta_5 (\ln \tau)^2], \quad (2)$$

where τ is calendar DTE in days, $m = K/S$ is moneyness with strike K and stock price S , and $\beta_1, \dots, \beta_5$ are fitted coefficients. The predicted squared IV for ticker i was then given by:

$$\hat{\sigma}_i^2(\tau, m) = \theta_i \psi(\tau, m), \quad \theta_i > 0, \quad \psi(\tau, m) > 0, \quad (3)$$

where θ_i sets the overall IV level of ticker i and ψ is either the parametric shape or a neural shape. The parametric fit estimated the shared coefficients and the ticker levels together by minimizing the same IV loss as the networks.

The neural surfaces replaced the polynomial with the output of a neural network (NN), given by:

$$\psi_{\text{NN}}(\tau, m; w) = \exp[\text{NN}(\text{std}(\ln \tau), \text{std}(\ln m); w)], \quad (4)$$

where w denotes the network weights and $\text{std}(\cdot)$ standardizes each input with the mean and standard deviation of the training rows. The global network pooled all tickers, and each sector network pooled the tickers of one sector. A ticker received its own network only if it had at least 2,000 observations, and tickers below that threshold kept their sector’s network. The global and sector networks all had two hidden layers of 16 tanh units ($2 \rightarrow 16 \rightarrow 16 \rightarrow 1$, 337 parameters). A single-ticker network had the same size if its ticker had at least 5,000 observations and two hidden layers of 8 units ($2 \rightarrow 8 \rightarrow 8 \rightarrow 1$, 105 parameters) otherwise. We fitted the network weights and the ticker log levels $\ln \theta_i$ jointly by minimizing the mean squared difference between predicted and reported

IV, which weights every retained observation equally. The loss was given by:

$$\min_{w, \{\ln \theta_i\}} \frac{1}{n} \sum_{j=1}^n \left[\sqrt{\theta_{i(j)} \psi_{\text{NN}}(\tau_j, m_j; w)} - \sigma_{\text{market}, j} \right]^2, \quad (5)$$

where n is the number of observations, $i(j)$ is the ticker of observation j , τ_j and m_j are its calendar DTE and moneyness, and $\sigma_{\text{market}, j}$ is its reported IV. We initialized each log level at twice the logarithm of the ticker's mean reported IV. Training used the Adam optimizer with a decreasing learning rate for at most 2,000 epochs, or full passes through the training data. It stopped after 200 epochs without improvement in training loss, and we kept the weights from the final epoch. A constant can move between $\ln \theta_i$ and the network's output bias without changing the fit, so the two are not separately identified. Only the predicted variance $\theta_i \psi$ in (3) can be interpreted without an extra normalization.

To test how well the surfaces transferred to dates withheld from fitting, we used two holdouts within the calibration window. The April earnings holdout is named for the earnings reports near its test dates. It trained a network pooled over all tickers on the six snapshots labeled April 14 through April 22 and tested it on the snapshots labeled April 23 and 24. The single-date holdout withheld the snapshot of the May 11 session and retrained the sector networks on the other fourteen. To test whether scheduled earnings reports explained errors in this holdout, we also trained the pooled network on the same split with two earnings inputs, built from earnings dates in the public Yahoo Finance calendar. The first input was the signed number of calendar days to the ticker's nearest earnings date, positive before the report and negative after it, clipped to $[-30, 30]$. The second was the smallest absolute number of days to an earnings date among the ticker's sector peers, clipped to 30. For the three ETFs, which report no earnings of their own, both inputs were the smallest absolute number of days to an earnings date among all 28 stocks. This network had 369 parameters ($4 \rightarrow 16 \rightarrow 16 \rightarrow 1$). The GS and LLY simulations never used the earnings inputs.

2.3 Daily IV updates

The daily IV update adapted the variance equation of the Heston model [Heston \[1993\]](#). In its standard form, that model pairs a stock-price diffusion with a square-root process for the stock's instantaneous variance. The variance reverts toward a long-run level, and its random changes scale with the square root of its current value. It follows the stochastic differential equation given by:

$$dv_t = \kappa(\bar{v} - v_t) dt + \sigma_v \sqrt{v_t} dW_t^v, \quad (6)$$

where κ is the mean-reversion rate, $\bar{v}$ is the long-run variance, σ_v is the volatility of variance, and W_t^v is a Brownian motion that the standard model correlates with the one driving the stock. We applied the same square-root equation to a different quantity. Each option received its own implied-variance state, which we call its IV factor. The factor is an implied variance, and its square root is the option's IV. For an option $a = (i, K, T)$ on ticker i with strike K and expiration T , the factor $v_{a,t}$ reverts toward a moving target in place of Heston's constant level $\bar{v}$. The target is read from the fitted surface and is given by:

$$\bar{v}_{a,t} = \theta_i \psi_{\text{NN}}(\tau_t, K/S_t), \quad (7)$$

where θ_i and ψ_{NN} are the fitted ticker level and neural shape for ticker i , S_t is the stock price on date t , and τ_t is the remaining calendar DTE on that date. The target therefore moves as the stock price and the time to expiration change. The GS and LLY illustrations and the IV ablation used the per-ticker networks, and the forecast test used sector networks refitted on data through July 31. When the stock moved so far that K/S_t left the fitted range of 0.8 to 1.2, the surface extrapolated, and we report how often this happened (Supplementary Table S14). Each factor started on the fitted surface on the entry date, April 28 in the illustrations:

$$v_{a,0} = \bar{v}_{a,0}. \quad (8)$$

The forecast test instead started each factor at the option's observed IV on the date the forecast was issued. On every date, the IV entering the option's binomial tree was the square root of the factor:

$$\sigma_{a,t} = \sqrt{v_{a,t}}. \quad (9)$$

Each pricing calculation held this IV constant, and the factor changed only between trading days. The factor is therefore the implied variance of one option, not the instantaneous variance of the stock's returns.

Each factor received a random shock on every trading day, partly tied to the stock's return. We first standardized the stock's daily log returns. The standardized return shock was given by:

$$Z_{j,t}^S = \frac{\Delta \ln S_{j,t} - \overline{\Delta \ln S}}{s_{\Delta \ln S}}, \quad (10)$$

where $\Delta \ln S_{j,t} = \ln(S_{j,t+1}/S_{j,t})$ is the log return on path j over the step from date t to date $t + 1$, and $\overline{\Delta \ln S}$ and $s_{\Delta \ln S}$ are a mean and standard deviation of these returns. In the GS and LLY illustrations, these two constants came from all simulated paths and dates. The IV ablation and the forecast test instead took them, together with the growth shift, from a separate pilot simulation run before the evaluation paths were drawn. No evaluation path was therefore standardized with its own later returns. The shock to each factor combined the return shock with an independent standard normal shock and was given by:

$$Z_{j,t}^v = \rho Z_{j,t}^S + \sqrt{1 - \rho^2} Z_{j,t}^\perp, \quad Z_{j,t}^\perp \sim \mathcal{N}(0, 1), \quad (11)$$

where ρ sets how strongly the factor responds to the stock's return. We fixed $\rho = -0.6$ by assumption rather than estimating it from market data, so IV tended to rise when the stock fell. On a given path and date, every option on the same stock received the same shock $Z_{j,t}^v$, so the put and the call in each illustration responded to the same random draws. Each option still kept its own factor and target, because the surface predicts a different IV at each strike and expiration. Each factor then advanced once per trading day by an Euler step of the square-root equation, with $\Delta t = 1/252$ and a floor at $v_{\min}$. The step used $Z_{j,t}^v$ in place of a normal Brownian increment, so the part of each shock tied to the stock inherited the non-normal shape of the JumpHMM returns. The floored step was given by:

$$v_{a,t+1} = \max \left\{ v_{a,t} + \kappa(\bar{v}_{a,t} - v_{a,t})\Delta t + \sigma_v \sqrt{\max(v_{a,t}, 0)} \sqrt{\Delta t} Z_{j,t}^v, v_{\min} \right\}, \quad (12)$$

where the path index j is omitted from $v_{a,t}$ and $\bar{v}_{a,t}$ for brevity. We fixed $\kappa = 15$ per year, $\sigma_v = 0.5$, and $v_{\min} = (0.005)^2$ as assumptions rather than estimates. With daily steps, $\kappa = 15$ closes about 6% of the gap between a factor and its target each trading day. The floor kept the factor positive for the pricer. It was needed because an Euler step can fall below zero even when the Feller condition, which keeps the continuous-time process positive, holds [Andersen \[2008\]](#). The simulation code also contains two optional features, a target that depends on JumpHMM's hidden state and a multiplier that raises the target during visits to tail states. Both were switched off in every analysis, so the fitted surface alone set the target and ρ alone linked the random shocks to stock returns.

2.4 American-option pricing and profit and loss

A binomial tree prices an American option by working backward from expiration and taking, at every node, the larger of the value of continuing and the value of exercising immediately [Cox et al. \[1979\]](#), [Broadie and Detemple \[1996\]](#). We used two such trees, each with one constant volatility at every node. The Cox–Ross–Rubinstein (CRR) tree sets its up and down moves from that volatility [Cox et al. \[1979\]](#). The Leisen–Reimer (LR) tree uses the Peizer–Pratt inversion to place its moves so that prices converge faster as steps are added, which gives the smooth prices that finite-difference Greeks need [Leisen and Reimer \[1996\]](#). Moment-matching trees such as those of Jarrow–Rudd and Tian [Jarrow and Rudd \[1983\]](#), [Tian \[1993\]](#) are further alternatives that we did not use. To turn fitted IVs into dollar prices for comparison with the quoted midpoints in the first analysis, we used a 200-step American CRR tree. All simulated prices and Greeks used a 201-step American LR tree, since the LR construction requires an odd number of steps. When the option's IV $\sigma_{a,t}$ was so small that $\sigma_{a,t} \sqrt{\tau_t/365} < 0.01$, with $\tau_t/365$ the time to expiration in years, or the LR tree gave no finite price, an American CRR tree with at least as many steps priced the option instead. Both trees priced options risk-neutrally with an assumed constant risk-free rate of 4.25%. This rate is separate from the zero rate that defines JumpHMM's growth rates, and the simulated stock paths followed JumpHMM's real-world growth rates rather than the risk-free rate. Both also set the dividend yield to zero ($q = 0$) for every ticker, although GS, LLY, and many other tickers pay dividends. We accepted both mismatches as simplifications. With no dividends and a positive rate, early exercise of an American call is never optimal, so the American feature mattered only for the puts.

The GS and LLY illustrations each simulated one put and one call, opened on April 28, 2026, and expiring on May 29, 2026. On April 28, GS closed at \$926.38, and its options had strikes of \$890

(put, $K/S = 0.961$) and \$970 (call, $K/S = 1.047$). For LLY, the close was \$873.83, and the options had strikes of \$825 (put, $K/S = 0.944$) and \$940 (call, $K/S = 1.076$). All four options were therefore out of the money. We studied short positions, sold at the indicative midpoints in the April 28 snapshot, whose label, download, and session dates all agree, because a seller can lose money before expiration even when the option expires worthless. The holding period covered 31 calendar days and 22 trading days after excluding weekends and the May 25 market holiday. The tree measured time to expiration in calendar days and received $\tau_t/365$ years, while the stock and the factors advanced in 22 daily steps of $\Delta t = 1/252$. The illustrations used 1,000 paths per ticker with seed 20260429. Each path started at the April 28 closing price, with its hidden state drawn from the stationary distribution of the transition matrix. Its 22 simulated returns then gave the prices on the 22 later trading days. Because the calibration window ran to May 11, the surfaces used in the illustrations and the IV ablation included quotes from after April 28, so these analyses illustrate the model rather than forecast. At expiration, the option's intrinsic value, its payoff from immediate exercise, replaced the tree price (Algorithm 1).

Algorithm 1 Forward simulation of contract values under the full factor; the other IV variants change only the factor update

Require: JumpHMM model for ticker i and growth shift c ; fitted $(\theta_i, \psi_{\text{NN}})$; contracts $a = (K, T, \phi)$, with $\phi = 1$ for a call and $\phi = -1$ for a put; trading dates $d_0, \dots, d_L$; calendar DTE $\tau_0, \dots, \tau_L$; (κ, σ_v, ρ) ; entry price S_0 ; risk-free rate r ; N_p paths; LR tree steps N_{LR} .

Ensure: Stock, IV-factor, IV, and option-value paths.

- 1: Draw N_p JumpHMM stock paths with L trading transitions and emissions truncated as in (1).
 - 2: Compute $Z_{j,\ell}^S$ by standardizing the simulated daily log returns as in (10), with constants from these paths or from a pilot simulation.
 - 3: Draw $Z_{j,\ell}^\perp \sim \mathcal{N}(0, 1)$ once per path and transition; set $Z_{j,\ell}^v \leftarrow \rho Z_{j,\ell}^S + \sqrt{1 - \rho^2} Z_{j,\ell}^\perp$ and reuse it for every contract.
 - 4: **for** contract a and path j **do**
 - 5: $v_{a,0}^{(j)} \leftarrow \theta_i \psi_{\text{NN}}(\tau_0, K/S_0)$
 - 6: **for** $\ell = 0$ **to** $L - 1$ **do**
 - 7: $\sigma_{a,\ell}^{(j)} \leftarrow \sqrt{v_{a,\ell}^{(j)}}$
 - 8: $P_{a,\ell}^{(j)} \leftarrow \text{LR}_{N_{\text{LR}}}(S_{j,\ell}, K, \sigma_{a,\ell}^{(j)}, \tau_\ell/365, r)$
 - 9: $\bar{v}_{a,\ell}^{(j)} \leftarrow \theta_i \psi_{\text{NN}}(\tau_\ell, K/S_{j,\ell})$
 - 10: Update $v_{a,\ell+1}^{(j)}$ with the floored Euler step in (12) using $\Delta t = 1/252$.
 - 11: **end for**
 - 12: $P_{a,L}^{(j)} \leftarrow \max\{\phi(S_{j,L} - K), 0\}$.

-

For a short position sold at premium p_0 , profit and loss (P&L) at expiration was given by:

$$\Pi_T^{\text{put}} = p_0^{\text{put}} - \max(K - S_T, 0), \quad \Pi_T^{\text{call}} = p_0^{\text{call}} - \max(S_T - K, 0), \quad (13)$$

where S_T is the JumpHMM stock price at expiration. We assumed entry at the observed midpoint, no transaction costs, no margin constraint, and no interest on the premium received. We also ignored early assignment. Each short position stayed open until expiration, or in the IV ablation until we closed it after five, ten, fifteen, or twenty trading days, even though the tree prices include the holder's right to exercise early. With early assignment ignored, the P&L at expiration depends only on S_T , the strike, and the premium, so the IV updates changed option prices and Greeks before expiration but not the payoff of a position held to expiration. All premiums, option values, and P&L are in dollars per share, so amounts for a standard 100-share contract are 100 times these values. We calculated the Greeks on the same LR tree by central finite differences, which reprice the option after equal upward and downward changes to one input. Delta measures the price's sensitivity to the stock price, gamma measures how delta changes with the stock price, and Vega measures the price's sensitivity to IV. Delta and gamma used stock-price bumps of $\pm 1.5\%$. Vega used IV bumps of ± 0.005 in absolute terms and is reported per volatility percentage point.

2.5 Comparison of five IV variants

To find which parts of the IV update changed option values before expiration, we repriced the GS and LLY options, sold at the same April 28 premiums, under five IV variants in the IV ablation. Within each seed, the five variants shared the same simulated stock paths. The first ablation seed equals the illustration seed, but the ablation set its growth shift from the pilot simulation, so its paths are not the illustration paths. Frozen IV kept each option's IV at its fitted entry value. The direct surface set the factor equal to its target, $v_{a,t} = \bar{v}_{a,t}$, on every date. Deterministic mean reversion used the update in (12) without shocks ($\sigma_v = 0$). The uncoupled stochastic factor added shocks unrelated to stock returns ($\sigma_v = 0.5$, $\rho = 0$). The full factor linked those shocks to stock returns ($\sigma_v = 0.5$, $\rho = -0.6$). All three variants that followed (12) used $\kappa = 15$. Every variant started from the same fitted entry IV, and the two stochastic variants reused the same independent normal shocks, so results could be compared path by path. We ran the ablation with three random-number seeds per ticker (the integers 20260429, 20260430, and 20260431) and 1,000 paths per seed. Its pilot simulation used 10,000 paths (seed 20260905) and the same 22 trading-day steps. It fixed the growth shift for the 10% target and the return mean and standard deviation before the evaluation paths were drawn.

We compared the variants by the P&L from closing each short position before expiration. The primary endpoint closed the position after ten trading days, on May 12 with 17 calendar days to expiration. Secondary endpoints closed it after five, fifteen, and twenty trading days. We used the direct surface as the baseline, because its IV sits exactly on the target that the three updating variants move toward. The P&L from closing early, and its difference from the direct surface on the same path, were given by:

$$\Pi_{a,t}^{(g,j)} = p_{a,0} - P_{a,t}^{(g,j)}, \quad D_{a,t}^{(g,j)} = \Pi_{a,t}^{(g,j)} - \Pi_{a,t}^{(\text{surface},j)}, \quad (14)$$

where g denotes the IV variant, j the shared stock path, $p_{a,0}$ the entry premium, and $P_{a,t}^{(g,j)}$ the option's tree price on date t . Because the premium is the market midpoint while later prices come from the tree, Π also includes the gap between the two at entry, and this gap cancels in D . For each variant, we reported the mean of Π , its standard deviation, its 5% quantile, and its 5% expected shortfall, defined as the mean P&L at or below that quantile. The Monte Carlo standard error of the mean paired difference was $s_D / \sqrt{N_p}$, where s_D is the standard deviation of D across the N_p paths, 1,000 per seed or 3,000 pooled. These standard errors measure simulation noise with the fitted models and pilot constants held fixed. Price differences on individual paths can cancel in the mean, so we also reported the mean absolute difference between each variant's price and the direct-surface price on the same path. We reported each seed separately and also pooled the 3,000 paths per ticker.

We checked that entry prices and payoffs at expiration agreed exactly across variants, as they must by construction. We also checked the numerical accuracy of the prices in between. For every variant, we compared 201-step and 401-step LR prices on the first twenty paths of every seed after ten and twenty trading days and recorded the largest absolute difference. The tree prices each option separately, so nothing forces prices to be consistent across strikes. We therefore priced calls and puts at eleven fixed strikes from 0.8 to 1.2 times the entry stock price, a check we call the strike audit. The audit ran within the first ablation seed. Each audit strike used the May 29 expiration and its own factor and target, driven by the same shocks as the GS or LLY options. The audit used the first fifty paths of the first seed at entry and after ten and twenty trading days, at both 201 and 401 steps. Entry, which all paths share, was checked once. Each ticker, variant, option type, and tree size therefore had 101 stock-price points, the entry price and fifty paths on each of two dates. At each of these points, we checked four conditions, and a violation's size was the dollar amount by which a condition failed. Each price had to lie between its intrinsic value and an upper bound, the stock price for a call and the strike for a put. As the strike increased, call prices could not rise and put prices could not fall. The price difference between adjacent strikes could not exceed the distance between the strikes (the vertical-spread bound). Prices had to be convex in strike, so no price could exceed the straight line between its neighbors. For all four checks, we counted violations larger than \$0.01 per share. Passing these checks is necessary, but not sufficient, for prices to be free of arbitrage across strikes. The audit compared strikes within one expiration on each date, so it did not test consistency across expiration dates.

2.6 Tests on later dates

The tests on later dates trained surfaces on data up to a cutoff and scored them on dates after that cutoff, using the calibration files together with the later files. They ran as two separate tests, which we call stages. The first stage asked how well a surface predicted IV on a new date when that date’s stock price was known. The second stage fitted surfaces through July 31, scored them on later IV quotes, and then used them to forecast option values, which also required forecasting the stock.

The first stage used 58 daily snapshots labeled April 14 through July 17, 2026, ordered by their folder labels, which kept the sessions in order, and filtered as the calibration data were. In each of 53 expanding-window folds, we refitted the sector networks from scratch on the first k snapshots, with the calibration architecture and training schedule, and predicted IV on the next snapshot, for $k = 5, \dots, 57$. The networks used the two surface inputs, moneyness and maturity, and each fold standardized them with its own training snapshots alone. Each prediction used the new date’s stock price to compute moneyness, so this stage measured the surfaces alone, without a stock forecast or an IV update. We scored each fold by the root mean squared error (RMSE) of its IV predictions. A separate script rebuilt this data set from the raw files and reproduced its 986,492 filtered observations. It also confirmed that every observation passed the stricter two-sided-quote checks applied in the second stage (Supplementary Table S19).

The second stage fitted one set of surfaces on data through July 31 (the July-cutoff surfaces) and kept later sessions for a final test. The first stage used the files as saved. Some files, however, had been downloaded during the next day’s trading hours, when the quotes were live but the stored price was still the previous close. The second stage therefore first checked when each file had been downloaded, a step we call the capture audit. The download script recorded each retrieval time in UTC along with the stored closing stock price. We accepted a file only if it was retrieved between 20:00 UTC on the date of the session whose close it stored and 13:30 UTC on the next trading day. For April through September, this window runs from the 4:00 p.m. New York close to the next 9:30 a.m. open. This rule admitted overnight downloads of a session’s close and excluded twenty ticker files downloaded again during trading hours (Supplementary Table S19). We kept the latest eligible file per ticker and session and removed duplicate rows for the same option within a file. This stage also required two-sided quotes, with a finite positive bid, an ask no lower than the bid, and positive displayed sizes. Surface fitting kept the calibration filters on IV and moneyness and required a positive DTE computed from the expiration and the session date, because the DTE stored in some files counted from the download date instead. Retrieval times record when each file was downloaded, not when each quote was set. Some quotes may therefore have been stale, and stock and option prices may come from slightly different moments. These timing gaps may affect every IV error and dollar-price error in this study.

Training used the 68 captured trading sessions from April 13 through July 31. As a guard against look-ahead, it also excluded any file retrieved after the end of July 31 (UTC). The July 31 files were downloaded that evening, before this limit. We fitted six sector networks once on 1,173,538 observations (Supplementary Table S19). They used the two-input sector architecture and training schedule of the calibration comparison, with seed 42 and at most 2,000 epochs. We saved each network’s final weights, ticker levels, and training-only standardization. The test sample contained 425,061 filtered IV observations from the 23 captured sessions between August 4 and September 4. No snapshots exist for August 3, the first session after the cutoff, or for August 20. We scored the July-cutoff surfaces on these observations by RMSE and by bias, the mean of predicted minus observed IV. The architecture, fitting window, fitted weights, and seed were all fixed before this test. After this test, we asked whether earnings reports explained its errors. Following a protocol written before the refit, we refitted the July-cutoff sector networks with and without the two earnings inputs, each under seeds 42, 43, and 44.

The forecast test compared simulated option values with later observations of GS and LLY options chosen on each forecast date. It issued forecasts on successive trading days, which we call forecast origins, from August 4 into early September. At each origin, it forecast one put and one call per ticker in each of two cohorts. The monthly cohort used options with 25 to 45 calendar DTE, taking the expiration nearest 31 DTE, and was scored one trading session later. The shorter-maturity cohort used options with 10 to 21 DTE, taking the expiration nearest 14 DTE, and was scored one and five sessions later. Within each cohort, we chose the strike nearest $K/S = 0.95$ for puts or 1.05 for calls. If two expirations were equally close to the target, we took the earlier one, and if two strikes were

equally close, we took the lower one. The choice used only data available at the origin. We matched each chosen option at its exact endpoint session and recorded a missing endpoint as missing, without substituting another option or date. The monthly cohort was our original design for both the one- and five-session horizons. The downloaded files, however, kept only the expirations nearest the 2-, 7-, 14-, 30-, and 45-day targets. Five sessions after selection, a monthly option had about 24 days left, between the 14- and 30-day targets. Other expirations lay closer to both targets, so this one was no longer saved. None of these options was therefore observed at five sessions (Supplementary Table S20). We therefore added the shorter-maturity cohort. Its options, chosen near the 14-day target, had about a week left five sessions later and were then nearest the 7-day target, so most of them stayed in the data. We made this change, and recorded it in the written analysis protocol for this test, before looking at aggregate forecast errors.

At each origin, the forecast used the latest observed stock price and option IVs, while the July-cutoff surfaces, the JumpHMM parameters fitted on 2014–2024 prices, and the IV-update constants stayed fixed. We drew 1,000 JumpHMM stock paths per origin, with a fixed seed for each origin, and every IV variant used the same shocks. The starting hidden state was drawn from the stationary distribution of the model’s transition matrix, with no jump episode in progress, so recent returns did not inform it. A separate 10,000-path pilot simulation for each ticker, reused at every origin, fixed the growth shift for the 10% target and the return mean and standard deviation before the evaluation paths were drawn. As a stock-only benchmark, a Gaussian random walk with zero log drift and the pilot’s return standard deviation also forecast each endpoint stock price. All five IV variants started from the IV that Alpaca reported for the option at the origin. To keep the fitted surface’s error in the starting IV level out of the comparison, we rescaled the surface target once at the origin. The rescaled target was given by:

$$\bar{v}_{a,t}^* = \sigma_{a,0,\text{obs}}^2 \frac{\bar{v}_{a,t}}{\bar{v}_{a,0}}, \quad (15)$$

where $\sigma_{a,0,\text{obs}}$ is the option’s observed IV at the origin and $\bar{v}_{a,t}$ is the target in (7) along each simulated path. This target started at the square of the observed IV and kept the surface’s relative changes with stock price and time to expiration. The rescaling applied only to the forecast test, and the IV ablation kept its fitted starting values. Frozen IV held the observed origin value, the direct surface followed $\bar{v}_{a,t}^*$, and the three updating variants reverted toward $\bar{v}_{a,t}^*$ with the IV-ablation parameters.

We scored the mean forecast option value against the later bid–ask midpoint, with mean absolute error (MAE) as the primary metric, fixed before the test. To check that conclusions did not depend on the choice of point summary, we also scored the median forecast. Signed error, RMSE, and the share of forecast means inside the quoted spread served as additional price diagnostics. To score the whole forecast distribution, we used the empirical continuous ranked probability score (CRPS) [Gneiting and Raftery \[2007\]](#). The CRPS rewards forecasts concentrated near the observed value and penalizes probability placed far from it, and it is given by:

$$\text{CRPS} = \frac{1}{N} \sum_{j=1}^N |P_j - y| - \frac{1}{2N^2} \sum_{j=1}^N \sum_{l=1}^N |P_j - P_l|, \quad (16)$$

where $P_1, \dots, P_N$ are the option values at the endpoint on the $N = N_p$ simulated paths, y is the observed midpoint, and smaller values indicate better forecasts. We also reported how often the central 90% interval of the simulated values contained the observed midpoint (coverage) and how wide that interval was. All monetary scores are in dollars per share. For each ticker, cohort, and horizon, we averaged the scores of the options matched at the endpoint on each origin, the put, the call, or both, and then averaged across origins. Overlapping horizons and shared market moves made the origins dependent, so the effective number of independent observations was smaller than the number of origins, and adding simulated paths could not increase it.

Two diagnostics located the sources of forecast error. The first repeated the IV updates along the realized stock path whenever every intervening session was observed. It standardized the realized returns with the pilot constants and still drew the independent shocks, so its option errors excluded the error of the stock forecast. The second priced each option at its endpoint in the 201-step LR tree, using the observed endpoint stock price and the IV that Alpaca reported at the endpoint. It then compared this price with the observed midpoint. Its errors measure how far the tree, given the reported IV, departs from the quoted price. We also scored the stock forecasts of the 1,000

JumpHMM paths and of the random walk at each endpoint. For the example forecast figure, we chose the earliest GS origin in the shorter-maturity cohort with both options observed at the five-session endpoint, a rule that did not depend on forecast errors.

2.7 Stock forecast benchmarks

After the forecast test, we evaluated JumpHMM’s stock forecasts on their own, with new 10,000-path runs separate from the forecast test’s 1,000 paths, because its stock forecasts had missed by more than expected. We first ruled out a coding mistake in how the paths were built. We confirmed that the simulated growth rates were converted to daily log returns with the $1/252$ step and compounded into prices once per day. We also rebuilt the prices from the saved growth rates and compared them with the simulated prices. Because the starting hidden state did not use recent returns, we next repeated the 2026 stock forecasts with the starting state drawn from the distribution that a forward filter inferred from all available past daily returns. The filter kept the fitted parameters, tracked both the hidden state and the days remaining in any jump episode in progress, and used the likelihoods of the truncated emissions in (1).

We then asked whether other stock forecast methods could make smaller errors without using future information. We compared four methods on equal terms, JumpHMM and the three described next. The JumpHMM forecasts started from the stationary distribution and used the pilot growth shift. The unchanged-price benchmark forecast the origin price itself and gave no uncertainty interval. The forecast test’s random walk and the filtered starting state served only as diagnostics and were not part of this comparison. The adaptive-volatility model drew Gaussian log returns with zero drift and updated its daily variance with an exponentially weighted moving average (EWMA) of squared log returns [J.P. Morgan/Reuters \[1996\]](#). The direction-predicting model kept that variance and added a daily drift predicted by a regression. The two models were given by:

$$a_t = \lambda a_{t-1} + (1 - \lambda)u_t^2, \quad \log \frac{S_{t+h}}{S_t} = h\mu_t + \sqrt{a_t} \sum_{j=1}^h Z_j, \quad Z_j \sim \mathcal{N}(0, 1), \quad (17)$$

where $u_t = \log(S_t/S_{t-1})$ is the observed daily log return, a_t is the estimated daily variance at origin t , λ is the EWMA decay, h is the horizon in trading days, and μ_t is the daily drift. The adaptive-volatility model set $\mu_t = 0$, and the direction-predicting model used the regression prediction, so the adaptive-volatility model is the direction-predicting model with zero drift. The regression predicted the next day’s log return divided by the EWMA volatility at the origin, and the drift μ_t was this prediction multiplied by that volatility. Its inputs were the stock’s cumulative log returns over its latest one, five, and twenty daily returns, and the cumulative log return of SPY over its latest five daily returns. The fund SPY tracks the S&P 500. Each input was divided by the square root of its window length and by its own asset’s EWMA volatility at the origin, so SPY’s input used SPY’s volatility. We fitted the regression separately for GS and LLY, without an intercept, and a ridge penalty shrank its coefficients toward zero [Hoerl and Kennard \[1970\]](#). Drift and variance stayed fixed within each forecast horizon, so neither model used future stock or market returns. Neither model used the return cutoff, which applies only to JumpHMM. These stock tests did not change the paths used in the option forecasts or the IV ablation.

We selected the settings of the adaptive-volatility and direction-predicting models on annual validation blocks from 2019 through 2024, using only data before each block to fit the regression and its input scaling. After the window and volatility scaling, each input column was also divided by its root mean square in the training data. We chose one EWMA decay and one ridge penalty for both tickers, weighting each ticker, validation year, and horizon (one and five sessions) equally. Candidate decays were 0.80, 0.90, 0.94, 0.97, and 0.99, and we chose the decay that minimized the Gaussian log loss of cumulative log returns. Candidate ridge penalties ranged from 0.01 to 1000 and included the zero-drift limit, an infinite penalty that sets every coefficient to zero. We chose the penalty that minimized the squared cumulative-return error divided by the forecast variance. After selection, we fitted the regression on 2014–2024 observations and froze its coefficients and input scaling.

We then tested all four methods in two later periods. The daily closes for 2014 through 2025 came from the S&P 500 daily price files included with the code, and the 2026 closes came from the closing prices stored in the option files. Because the 2026 closes begin in April, the EWMA variance restarted in April from its 2014–2024 estimate. The 2025 test supplied 249 one-session and 245 five-session origins per ticker. The August–September 2026 test used the option-test origins with

an observed stock price at the endpoint, 21 at one session and 17 at five sessions per ticker. All methods used identical starting prices and endpoints. Features and variance at each origin used only data available at that time. A missing daily close was left as a gap, so every return spanned exactly one trading day. Each stochastic method used 10,000 paths per origin for each of three fixed seeds. The adaptive-volatility and direction-predicting models shared the same Gaussian shocks. We reported the MAE of the median forecast and the RMSE of the mean forecast, because the median minimizes expected absolute error and the mean minimizes expected squared error [Hyndman and Athanasopoulos \[2021\]](#). The option forecast test, by contrast, fixed MAE of the mean in advance as its primary score. For the three methods with forecast distributions, we also reported CRPS and the coverage and width of central 90% intervals. Scores were averaged across dates within each simulation seed and then across seeds. We proposed the adaptive-volatility and direction-predicting models after seeing JumpHMM’s August and September 2026 stock-forecast errors, although their settings came from the 2019–2024 validation blocks. We therefore reported the two periods separately and treated the 2026 comparison as exploratory.

3 Results

To test whether IV surfaces could serve as targets, we fitted parametric and neural surfaces to the calibration data and observed lower in-sample error as the surfaces became more flexible and were shared by fewer tickers (Table 1). The filtered data contained 234,549 observations from 31 tickers across fifteen snapshots and six market groups (Supplementary Tables S2 and S1). Every model used the same loss and kept a separate level for each ticker. Root mean squared error (RMSE) measured agreement with reported IV in volatility percentage points. Replacing the global parametric shape with a global neural surface reduced pooled in-sample error from 12.48 to 11.47 points. Sector networks reduced it further, to 10.24 points. They improved all six groups, most in exchange-traded funds (ETFs) and financials (Supplementary Table S3). Technology and healthcare kept the largest errors and contained the weakest individual ticker fits (Supplementary Table S7). These remaining differences motivated separate surfaces for tickers with enough observations. Giving each such ticker its own network, while keeping sector networks for the rest, reduced pooled error to 9.73 points. This error was 22% below that of the parametric surface, and most qualifying tickers improved (Supplementary Table S4). We next asked whether the fits held on individual dates, in dollar prices, and on later dates.

Table 1: In-sample IV RMSE of parametric and neural surfaces on 234,549 observations, in volatility percentage points. Each model fitted one ticker level jointly with its shape parameters. The final row used per-ticker neural surfaces for the 29 qualified tickers and sector surfaces for PFE and BMY.

Model	RMSE	Reduction from parametric
Parametric shape, global	12.48	reference
Neural shape, global	11.47	8.1%
Neural shape, six sectors	10.24	17.9%
Neural shape, per-ticker with fallback	9.73	22.0%

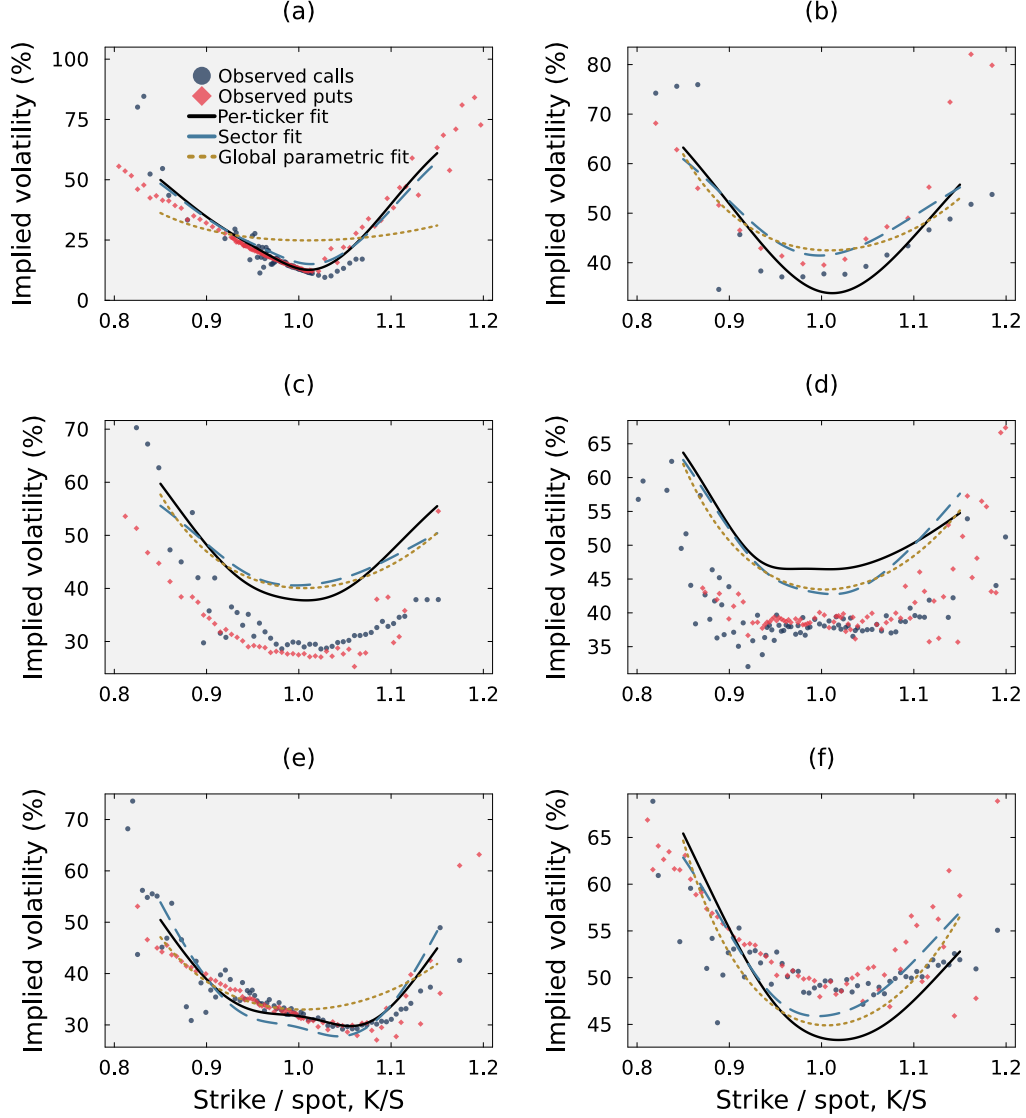

Figure 1: In-sample comparison of the implied volatility (IV) observed on May 11, 2026 with surfaces fitted across all fifteen calibration snapshots. Panels show (a) SPY, (b) NVDA, (c) MSFT, (d) LLY, (e) GS, and (f) AVGO, with 7, 7, 9, 11, 11, and 9 calendar days to expiry, respectively. Circles and diamonds distinguish reported call and put IV. Solid, dashed, and dotted curves show per-ticker neural, sector neural, and global parametric fits. The legend applies to all panels. The MSFT and LLY fits overpredict IV near the money (Supplementary Table S5).

We first compared the fitted surfaces with the observations on a single date, May 11, and found errors in the overall IV level that carried into option prices (Figs. 1 and 2). The surfaces had been fitted on all fifteen snapshots, including May 11, so the comparison was in-sample. Near the money, the per-ticker fits exceeded observed IV by an average of 9.45 percentage points for MSFT and 7.90 points for LLY (Fig. 1; Supplementary Table S5). The biases were small for SPY and GS, whereas the fit underpredicted AVGO by 5.37 points. These errors occurred at quoted contracts, not in extrapolated parts of the surface. A surface whose only inputs are moneyness and maturity cannot shift its level for one date. To measure the effect on prices, we priced each option with its fitted IV in the American tree and compared each dollar error with the local bid-ask half-spread. We used the half-spread because the same IV error moves prices by different amounts across contracts. Only about one third of the fitted SPY, NVDA, and LLY prices fell within the half-spread around the mid,

compared with 88% for GS (Fig. 2; Supplementary Table S6). The largest median absolute error, \$4.01 per share, was for LLY. Repeating the calculation with each contract’s reported IV in the same tree cut the LLY median error six-fold, to \$0.67 per share. The surface’s IV level on that date was therefore a major source of the price error. Even with the reported IV, the American tree missed some captured mids. A better pooled fit still left errors on individual dates, and dollar prices needed a check of their own.

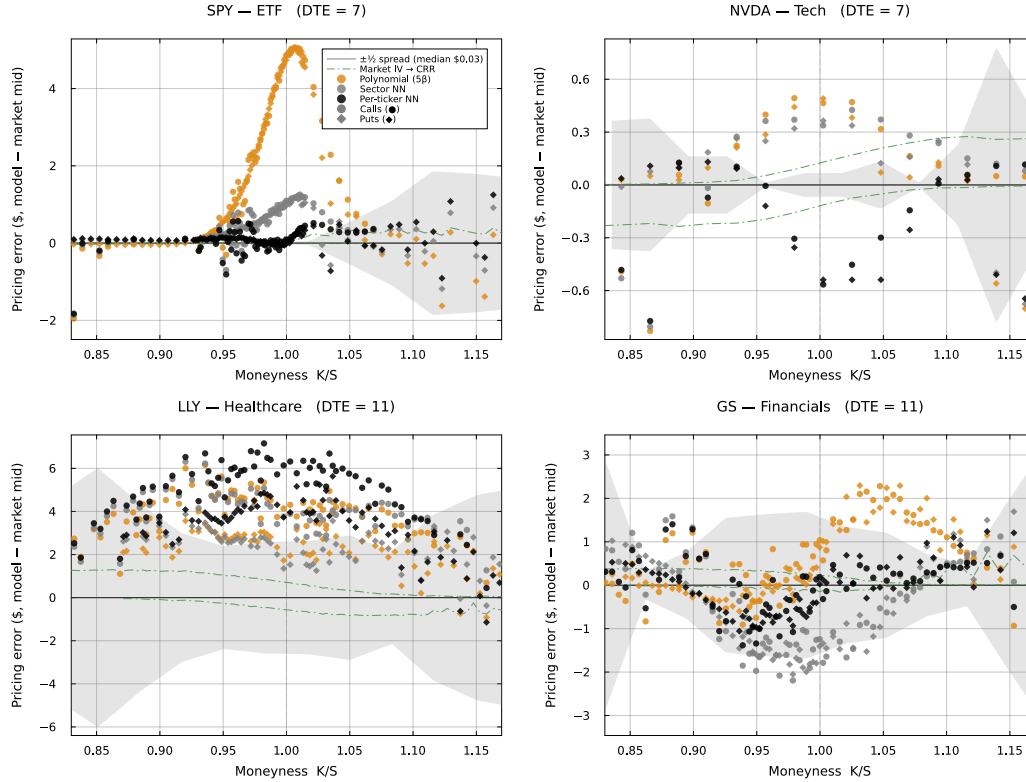

Figure 2: In-sample comparison of CRR American-option prices with Alpaca indicative mids across moneyiness for SPY, NVDA, LLY, and GS on May 11, 2026. Errors are tree price minus indicative mid. Curves show prices from the parametric, sector, and per-ticker surfaces and, for reference, from the reported IV. The gray ribbon is the median local bid-ask half-spread by moneyiness bin. A point inside the ribbon has an absolute pricing error below that local half-spread.

Because the May 11 comparison was in-sample, we next withheld dates from training and observed higher errors on those dates, which earnings-calendar inputs reduced on one fixed holdout (Table 2). One test removed May 11 and retrained the sector networks on the other fourteen dates. Pooled error was 10.21 volatility percentage points on the training data and 10.89 points on the held-out date (Supplementary Table S8). Error rose most in energy and retail, so the small pooled gap hid differences among sectors. A separate temporal split then tested whether calendar inputs added information beyond moneyiness and maturity. Configuration A used those two inputs alone. Configuration C added the distances to the ticker’s and its peers’ earnings dates, on exactly the same training and test rows. The added inputs reduced error on the two-day holdout from 13.03 to 11.98 volatility percentage points. Several technology tickers with nearby peer reports improved, although not every ticker did (Supplementary Table S9). Configuration B instead removed observations near earnings before fitting the two-input model, and its training and test errors were similar. Because it discarded most observations and changed both samples, it could not isolate earnings as the cause of the original gap. Transfer to new dates was therefore limited, and earnings inputs helped on the one holdout tested.

Table 2: Temporal-holdout errors for three surface configurations. Training used six snapshots labeled April 14 through April 22, 2026, and testing used April 23–24. Every test ticker appeared in training. Errors and gaps are in volatility percentage points. Configuration B used different row sets from A and C.

Configuration	N_{tr}	N_{te}	Train RMSE	Test RMSE	Gap
A: pooled, two inputs	103,897	26,833	8.05	13.03	+4.99
B: non-earnings, two inputs	29,383	4,516	8.02	7.96	−0.06
C: earnings-aware, four inputs	103,897	26,833	7.61	11.98	+4.36

We then turned to the simulator, with the fitted surfaces as targets, and observed that simulated GS option values tracked the stock, while the put and call IV followed different paths (Figs. 3 and 4). We selected one put and one call for each of GS and LLY from the April 28 capture, all expiring on May 29 (Supplementary Tables S11 and S12). The original illustrations used 1,000 stock paths per ticker and a separate IV factor for each option, with the fixed settings in Supplementary Table S10. Before expiration, the put and call factors followed different targets as moneyness and calendar DTE changed (Fig. 4). The LLY paths used the same calculation with LLY’s own fitted return distribution and a higher fitted IV level (Supplementary Figs. S2 and S3). For both tickers, the Greeks along each path showed delta approaching ± 1 on paths heading toward exercise, gamma concentrating near the strike, and Vega declining toward expiration (Supplementary Figs. S1 and S4). Because the surfaces included observations from the scenario period, these paths illustrated how the model behaves. The tests on later dates evaluated forecasts with separately fitted surfaces.

We next held each short position to expiration and observed that the seller usually kept the full premium but faced losses in the lower tail (Supplementary Tables S11 and S12). For GS, the short put kept its full premium on 74.0% of paths and the short call on 67.7%. The worst 5% of outcomes, however, lost at least \$58.96 per share for the put and \$86.18 for the call. These tail losses were 3.6 and 5.4 times the entry premiums, and they left mean P&L positive for the put but negative for the call. The market heuristic $1 - |\Delta|$, which estimates the chance of keeping the premium from the quoted delta, gave 70.5% and 67.2% for the same contracts. For LLY, the put and call kept their premiums on 80.7% and 79.3% of paths, and both had positive mean P&L. These frequencies exceeded the heuristic by 11.0 and 10.2 percentage points, larger gaps than in GS. Agreement between the heuristic and the simulated frequencies therefore depended on the ticker and scenario. Quote delta comes from a risk-neutral pricing calculation, whereas the simulated frequencies came from real-world stock paths. Because P&L at expiration depended only on the stock path, strike, and premium, these results reflected the return model and the contracts, not the IV updates. Testing the IV updates required changing them while holding the stock paths fixed.

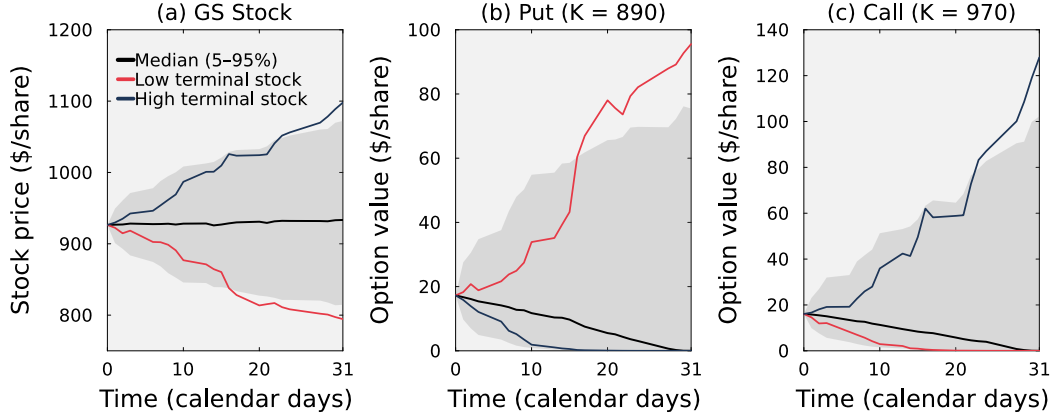

Figure 3: Simulated evolution of GS stock prices (a), put values (b), and call values (c) along 1,000 paths between April 28 and May 29, 2026. Time is measured in calendar days from April 28. Black curves show the median at each date, and shaded bands contain the middle 90% of values. Red and blue curves show group medians for paths ranked in the 1st–5th and 95th–99th percentiles of terminal stock price. Option values are dollars per share and represent the cost of repurchasing the contract for a short seller. Entry premiums were \$16.51 per share for the put and \$16.09 for the call.

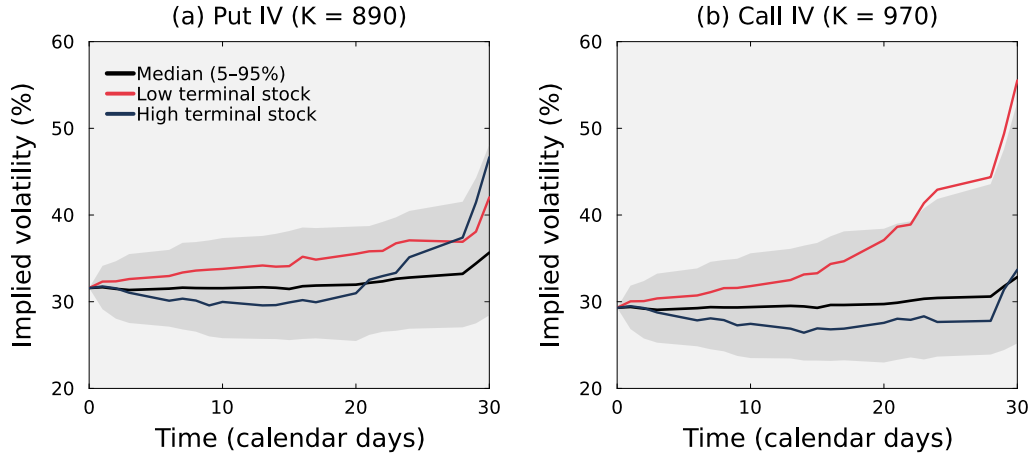

Figure 4: Simulated evolution of annualized IV at the GS put strike (a) and call strike (b) in the scenario of Fig. 3. Both panels express IV as percentages on the same vertical scale. Curves show pointwise medians across all 1,000 paths and within the terminal-stock groups defined in Fig. 3. Shading shows the 5th–95th percentile band. Time is measured in calendar days from April 28, 2026, and stops before expiration because the payoff at expiration does not depend on IV.

We therefore repriced the four scenario options under five IV variants on identical stock paths and found that the IV update changed option values before expiration and the lower tail of early-closing P&L (Fig. 5; Supplementary Table S13). The variants ranged from frozen IV to the full factor, and we measured each against the direct surface on the same paths. Contracts, entry premiums, and pricing assumptions stayed fixed, so any price difference came from the IV update. After ten trading days, the full factor’s prices differed from those of the direct surface by a mean absolute \$1.77–\$2.41 per share across the four options. These mean absolute differences were similar across the three evaluation seeds (Supplementary Table S14). For the GS put, the \$1.77 mean absolute change was about 38 times the \$0.047 decrease in mean P&L. That decrease had a paired Monte Carlo standard error of \$0.04. Positive and negative differences therefore largely canceled across paths. Frozen IV and deterministic mean reversion also gave prices that differed from the direct surface. The moving target, and the lag with which the factor followed it, thus affected prices even without random shocks. Comparing the full factor with the uncoupled stochastic factor on the same paths isolated the effect of linking IV shocks to stock returns (Fig. 5). For both tickers, short-put P&L declined most on falling-stock paths, and short-call P&L improved most on rising-stock paths. Coupling also changed the lower tail of short-position P&L. We measured this tail by the 5% expected shortfall, where more negative values mean larger losses. Negative coupling moved the GS put’s expected shortfall from $-\$62.98$ under the uncoupled factor to $-\$64.60$ under the full factor. The GS call’s expected shortfall improved from $-\$71.53$ to $-\$69.82$. The LLY options moved in the same directions (Supplementary Table S13). All variants gave identical entry prices and payoffs at expiration, so an analysis of payoffs at expiration alone would have missed these differences.

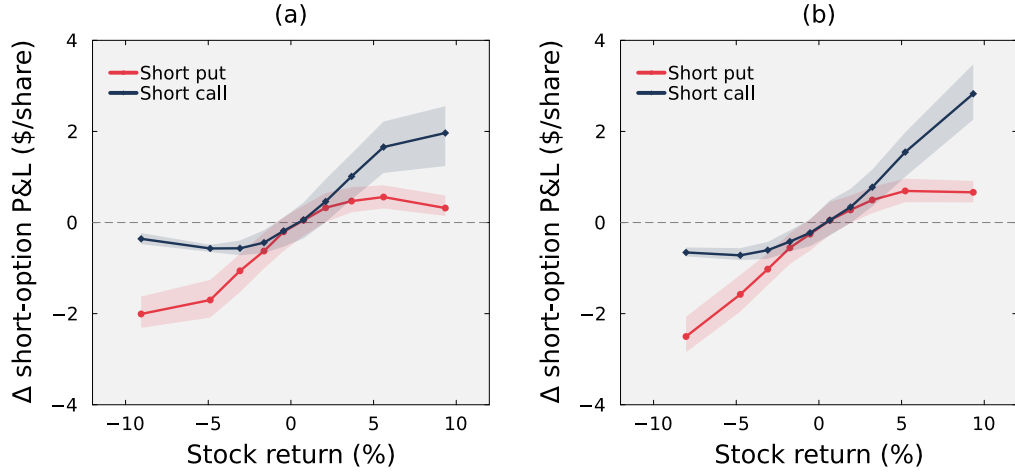

Figure 5: Effect of linking IV shocks to stock returns on short-option P&L before expiration, by stock return, after ten trading days for (a) GS and (b) LLY. Each difference is full-factor P&L ($\rho = -0.6$) minus uncoupled-factor P&L ($\rho = 0$) on the same stock path, with the same independent normal shocks. Negative values indicate worse short-position P&L under coupling. The 3,000 paths per ticker are sorted by stock return and divided into ten groups of 300. Symbols show each group’s median P&L difference at its median stock return, and lines connect the symbols. Shaded bands span each group’s 25th–75th percentiles. These bands describe variation across paths, not confidence intervals. Red circles denote puts and navy diamonds denote calls. All prices are evaluated on May 12, 2026, with 17 calendar days to expiration.

We then refined the tree and compared prices across strikes, and found that the variant differences exceeded numerical error but that some GS prices violated necessary strike conditions (Supplementary Tables S14 and S15). Increasing the tree from 201 to 401 steps changed sampled prices by at most \$0.0017 per share (Supplementary Table S14). That change was more than two orders of magnitude below the mean absolute differences among IV variants (Supplementary Table S13). No factor reached the variance floor in the four scenario options (Supplementary Table S14). However, strike/spot left the training interval on 0.7–2.9% of path dates before expiration, across tickers, options, and seeds. On those dates, prices used extrapolated surface values (Supplementary Table S14). Each convexity violation corresponds to a butterfly spread priced below zero. At 401

steps, the GS direct surface exceeded the \$0.01 convexity tolerance in 178 of 1,818 tested strike triples, and the largest excess was \$0.113 per share (Supplementary Table S16). The GS full factor had three monotonicity violations among 2,020 adjacent-strike comparisons, with a maximum of \$0.013 (Supplementary Table S16). These violations appeared at both tree depths (Supplementary Table S16). No LLY variant violated the tested conditions at the stated tolerance. Pricing each option accurately on its own therefore did not make the GS prices consistent across strikes.

To test forecasts of later option prices, we first extended the surface evaluation beyond the original April–May window and observed uneven accuracy on later dates (Supplementary Tables S17 and S18). In the expanding-window test, two-input sector networks predicted 53 successive held-out capture dates through July 17. The median test RMSE was 9.92 volatility percentage points, but individual folds ranged from 7.68 to 19.25 points (Supplementary Table S17). We then fitted one set of sector surfaces on data through July 31 (the July-cutoff surfaces) and scored them on the 23 later sessions from August 4 through September 4. Pooled RMSE rose from 10.79 points in training to 14.75 points on the held-out sessions (Supplementary Table S18). The fitting window, capture audit, and evaluation dates differed from those of the earlier folds, so the two sets of errors could not be compared directly. For GS, the held-out RMSE was 6.30 points, and the surface overpredicted IV by 0.88 points on average. For LLY, the held-out RMSE was 9.96 points, and the average overprediction of 4.61 points was more than five times the GS bias (Supplementary Table S18). Even with the larger data set, a fixed surface level still lagged later market IV. This lag motivated a separate forecast comparison in which all IV variants started from the observed IV at the forecast origin and differed only in how they evolved afterward.

We next compared option forecasts with later observations of the same options and found nearly identical errors under the full factor and frozen IV (Table 3). None of the 36 eligible roughly one-month options per ticker was observed again five sessions later, so these options were scored after one session only (Supplementary Table S20). That comparison kept 34 quotes across 17 origins per ticker. After one session, the full factor’s MAE was \$3.79 per share for GS and \$6.08 for LLY, compared with \$3.80 and \$6.11 under frozen IV (Supplementary Table S21). Five-session outcomes came from the shorter-maturity cohort, which supplied 34 GS and 30 LLY quotes across 17 origins per ticker. Coupling again reduced the MAE of the forecast mean only slightly. For GS, the MAE fell from \$4.21 under frozen IV to \$4.19, and for LLY it fell from \$11.62 to \$11.59. The full factor had lower date-level MAE than frozen IV on six of seventeen GS origins and nine of seventeen LLY origins (Table 3). These small average reductions were therefore not consistent across dates. Scoring the forecast median instead of the mean lowered the GS full-factor MAE to \$2.48 and gave an LLY MAE of \$11.79. Both values were again close to those under frozen IV (Supplementary Table S25). The full factor’s CRPS was also close to that of frozen IV, at 2.01 versus 2.02 for GS and 8.93 versus 8.99 for LLY (Table 3). Under the full factor, date-weighted coverage of the central 90% intervals was 100% for GS but 67.6% for LLY. The LLY coverage was 22 percentage points below the nominal level. At the earliest eligible GS origin, the full-factor and frozen-IV mean forecasts nearly coincided, while the observed call value fell below both (Fig. 6).

Table 3: Five-session option forecasts for the shorter-maturity cohort, selected with 10–21 calendar DTE at each origin. Scores average matched options within each ticker and origin before averaging dates. The MAE scores the forecast mean. Monetary quantities (MAE, CRPS, and central 90% interval width) are in dollars per share, and coverage is date-weighted. Dates better counts the origins on which a variant’s date-level MAE was below that of frozen IV. Every IV variant uses the same stock paths, origin IV, and matched quotes.

Ticker	IV variant	Dates	Quotes	MAE	CRPS	Coverage (%)	Width	Dates better
GS	Frozen IV	17	34	4.21	2.02	100.0	25.64	–
GS	Direct surface	17	34	4.86	2.16	67.6	24.01	2/17
GS	Mean reversion	17	34	4.26	2.02	100.0	25.62	1/17
GS	Uncoupled factor	17	34	4.24	2.03	100.0	25.69	3/17
GS	Full factor	17	34	4.19	2.01	100.0	25.65	6/17
LLY	Frozen IV	17	30	11.62	8.99	73.5	28.98	–
LLY	Direct surface	17	30	11.62	9.05	55.9	26.68	7/17
LLY	Mean reversion	17	30	11.62	8.99	73.5	28.83	7/17
LLY	Uncoupled factor	17	30	11.61	8.97	73.5	28.83	9/17
LLY	Full factor	17	30	11.59	8.93	67.6	28.91	9/17

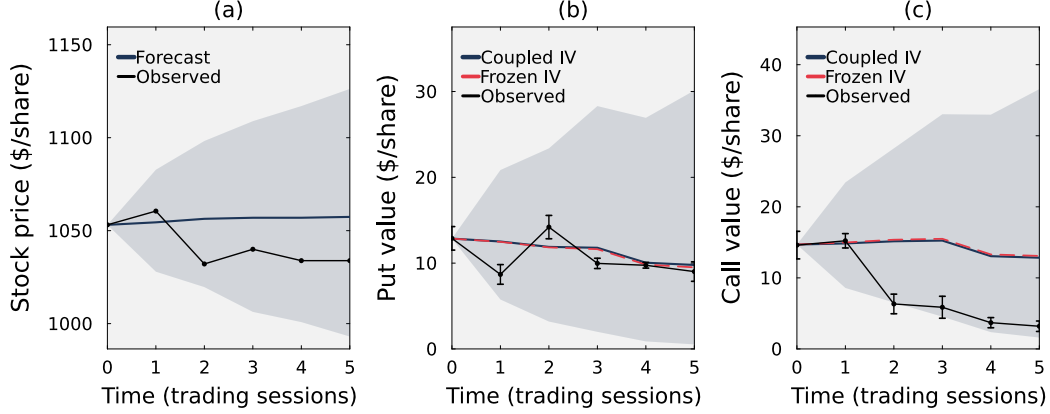

Figure 6: Five-session forecasts of GS stock prices (a), put values (b), and call values (c), compared with observations from August 4 to August 11, 2026. The put strike is \$1,000, the call strike is \$1,105, and both options expire on August 21. Forecasts use the July-cutoff surface and information available at the August 4 origin. Navy curves show forecast means from 1,000 stock paths, with the full factor used for option values. Shading spans the central 90% of simulated values. Red dashed curves show frozen-IV mean option forecasts on the same stock paths. Black points show observed stock closes and option midpoints, with vertical bars spanning Alpaca’s indicative bid and ask. Time is measured in trading sessions from the origin. August 4 was the earliest GS origin with both selected shorter-maturity options observed at the five-session endpoint.

To find where these errors came from, we replaced the simulated stock paths with the observed paths and found that stock-forecast error accounted for most of the option-price error (Supplementary Table S22). This substitution was possible for thirteen five-session origins per ticker, on which every intervening stock price was observed. These origins gave 26 matched GS quotes and 24 LLY quotes. In these cases, the substitution cut the full-factor MAE 3.8-fold for GS, from \$4.62 to \$1.23 per share. For LLY, it cut the MAE 5.4-fold, from \$10.61 to \$1.95 (Supplementary Table S22). Because the observed path was unknown at the origin, the substitution served only as a diagnostic that located the source of the error. Within the diagnostic, frozen IV had lower point errors than the full factor, at \$1.07 for GS and \$1.74 for LLY. The uncoupled stochastic factor had lower CRPS than the full factor for both tickers. For the stock itself, JumpHMM also gave no point-forecast advantage over a Gaussian random walk. Scored on its mean forecast, its five-session stock MAE was \$16.85 for GS and \$49.83 for LLY, compared with \$16.17 and \$48.64 for the random walk (Supplementary Table S23). A second diagnostic repriced each shorter-maturity option at its endpoint with its reported IV, which reduced five-session option MAE to \$0.14 for GS and \$0.34 for LLY. Every repriced value lay within its observed bid-ask interval (Supplementary Table S24). Refining the tree on sampled paths changed prices by at most \$0.0026 per share across the two cohorts, below the forecast errors (Supplementary Table S26). Stock-forecast error therefore dominated the option-price misses, and smaller errors remained in the IV and pricing inputs. No IV variant was reliably better than the others.

We next tested whether other stock forecasts could reduce these misses without future information and found that every tested method forecast stock prices about as accurately as an unchanged-price benchmark (Table 4). Before comparing methods, we checked how the JumpHMM forecasts scaled returns and rebuilt prices from the saved paths, and found no error in converting annualized log growth to daily prices. Inferring the starting state from recent returns did not materially improve five-session median forecasts. In these reruns, which used their own seeds, the median-based stock MAE changed from \$16.28 to \$16.36 for GS and from \$49.58 to \$49.40 for LLY (Supplementary Table S29). Under the fitted transitions, the starting state’s influence on the forecast distribution largely disappeared within a few sessions. We then compared JumpHMM with the unchanged-price benchmark, the adaptive-volatility model, and the direction-predicting model, using earlier data to select the settings of the last two. Validation on 2019–2024 data selected an EWMA decay of 0.97 and the zero-drift limit of the direction-predicting model’s regression (Supplementary Table S30). Under this criterion, the stock and SPY return features added no signal about direction, so the direction-predicting forecasts were identical to the adaptive-volatility forecasts. Testing the

models with fixed settings in 2025 supplied 245 five-session origins per ticker, more than fourteen times the 17 in the 2026 case study. In both periods, median-forecast errors stayed close to those of the unchanged-price benchmark. The RMSE of the mean forecast was also close to that of the benchmark (Supplementary Table S31). One-session forecasts likewise showed little separation in central price error from an unchanged-price forecast (Supplementary Table S32).

Table 4: Five-session stock forecasts in 2025 and August–September 2026. Each ticker has 245 origins in 2025 and 17 in 2026. The MAE scores the forecast median. Monetary quantities (MAE, CRPS, and central 90% interval width) are in dollars per share. Scores average dates within each of three 10,000-path simulation seeds and then average the seeds. Adaptive volatility denotes the Gaussian model with EWMA decay 0.97 selected on historical data. Historical selection set the direction-predicting model’s drift to zero, which made it identical to the adaptive-volatility model, so the table omits it. The unchanged-price benchmark has no uncertainty interval. The last column counts origins on which the adaptive-volatility model had lower date-level CRPS than JumpHMM.

Year	Stock	Model	Median MAE	CRPS	Coverage (%)	Width	Dates with lower CRPS
2025	GS	JumpHMM	22.31	16.22	84.4	84.71	–
2025	GS	Unchanged	22.61	22.61	–	–	–
2025	GS	Adaptive volatility	22.62	16.32	89.8	94.86	103/245
2025	LLY	JumpHMM	39.10	29.60	69.9	100.40	–
2025	LLY	Unchanged	39.37	39.37	–	–	–
2025	LLY	Adaptive volatility	39.35	28.57	84.4	151.37	131/245
2026	GS	JumpHMM	16.25	13.03	100.0	129.05	–
2026	GS	Unchanged	15.51	15.51	–	–	–
2026	GS	Adaptive volatility	15.48	15.58	100.0	176.18	2/17
2026	LLY	JumpHMM	49.44	35.60	70.6	147.26	–
2026	LLY	Unchanged	49.37	49.37	–	–	–
2026	LLY	Adaptive volatility	49.31	33.81	94.1	191.38	10/17

Because these point forecasts did not separate the methods, we then scored the full forecast distributions and found a ticker-dependent benefit from the adaptive-volatility model (Table 4). In 2025, LLY’s five-session CRPS fell from 29.60 under JumpHMM to 28.57 under the adaptive-volatility model. Coverage of the central 90% interval rose from 69.9% to 84.4%. Average interval width grew from \$100.40 to \$151.37, so the coverage gain came with a wider range of predicted prices. The lower CRPS showed that this trade-off improved the distribution score, although coverage stayed below its nominal level. In 2026, the LLY forecasts changed in the same direction. Their CRPS fell from 35.60 to 33.81, and their coverage rose from 70.6% to 94.1%. The adaptive-volatility model had lower date-level CRPS on 131 of 245 LLY origins in 2025 and on ten of seventeen in 2026 (Table 4). For GS, however, CRPS rose slightly in 2025, from 16.22 to 16.32. In 2026, it rose by 20%, from 13.03 to 15.58. Both GS models covered every 2026 endpoint, but the adaptive-volatility intervals were wider. The adaptive-volatility model therefore gave LLY forecast ranges that covered more outcomes and scored better, while its median forecasts stayed close to an unchanged price.

Finally, because every JumpHMM simulation used the return cutoff b , we widened the cutoff and observed small changes in the loss and forecast summaries (Supplementary Tables S34 and S35). We raised the cutoff from $b = 10$ to $b = 20$ and repeated the scenario, ablation, forecast, and stock-benchmark simulations. Across all fitted states, each cutoff implied daily return limits for each stock (Supplementary Table S33). In the original GS and LLY illustrations, the wider cutoff changed mean short-call P&L at expiration by less than \$0.02 per share and its 5% expected shortfall by less than \$0.07. At the ablation’s ten-day endpoint, it changed the full factor’s mean call P&L by less than \$0.004 and its expected shortfall by less than \$0.02 (Supplementary Table S34). In the forecast comparisons, five-session full-factor option MAE changed by less than \$0.007 per share. The reported stock CRPS values changed by less than \$0.002 (Supplementary Table S35). The wider cutoff therefore did not change the conclusion of any forecast comparison.

4 Discussion

How IV was set mattered before expiration, even when the stock paths stayed the same. We held a chosen stock-return model fixed, here the jump hidden Markov model JumpHMM, and repriced American options along identical stock paths under five ways of setting IV. One held IV fixed at

its starting value (frozen IV), and another set IV each day to the fitted surface’s prediction, which we call the target. The other three moved IV partway toward that target each day, either without random shocks, with independent random shocks, or with random shocks linked to stock returns (the full IV update). The choice changed option values and the outcome of closing short positions early, whereas starting values and payoffs at expiration agreed exactly. This made the experiment a controlled comparison of the IV assumptions. These differences matter because option positions are managed on every date before expiration, and an analysis of payoffs at expiration alone would miss them. The mechanics of the IV update in (12) explain these differences. The update used a mean-reversion rate of $\kappa = 15$ per year and daily steps. Each trading day therefore closed about 6% of the gap between an option’s implied variance (the square of its IV) and the variance predicted by the fitted surface. Half of any gap remained after about eleven trading days, so the version without random shocks lagged behind a target that moved with the stock price and the time to expiration. We measured each version’s prices and profit and loss (P&L) against the version that set IV directly to the target. After ten trading days, the P&L differences for the version without shocks were at least three quarters as large as those for frozen IV (Supplementary Table S13). Over ten days, that version therefore stayed closer to frozen IV than to the target. Adding random shocks had a different effect, because the shocks averaged zero. For the GS put, the average absolute difference from the price with IV set directly to the target rose from \$0.42 without shocks to \$1.75 with independent shocks. The average P&L difference, however, changed by only \$0.06 between these two versions. Price changes on individual paths were large, but they canceled across paths and left average P&L nearly unchanged. Linking the shocks to stock returns with a negative coefficient raised IV after the stock fell and lowered it after the stock rose. Stock volatility tends to move the same way, rising after prices fall, a pattern known as the leverage effect Cont [2001]. This link raised put values on falling-stock paths, where short puts already lost money, and lowered call values on rising-stock paths, where short calls lost money. Compared with independent shocks, the link therefore increased the average loss in the worst 5% of outcomes (expected shortfall) for short puts on both GS and LLY and reduced it for short calls.

The forecast tests asked whether the simulator also predicted later market prices of the same options. With its parameters held fixed, the full IV update reduced the mean absolute error of the mean option forecast only slightly relative to frozen IV (Table 3). This small advantage was not consistent across dates, and it did not persist when forecasts were summarized by the median instead of the mean (Table 3; Supplementary Table S25). The full update’s central 90% price ranges contained every observed GS price but only about two thirds of LLY prices. The slow adjustment toward the target limited what the IV update could add over five trading days. All five versions started from the IV observed on the forecast date. Each option’s target was rescaled to equal that IV on that date, so gaps opened only as stock moves and the passage of time changed the target. The update closed only about a quarter of any such gap in five days. The changing target and the random shocks also raised IV on some paths and lowered it on others. Averaged across paths, the updated IV therefore stayed within 0.3 volatility points of its starting value, although individual paths moved about 2.5 points (Supplementary Table S27). Frozen IV kept the starting value throughout, so the two average option forecasts stayed close. An update with fixed parameters that pulls IV toward a fixed surface carries no information about future IV beyond how the surface’s prediction changes with moneyness and time to expiration. Observed IV surfaces, by contrast, shift over time. Index-option surfaces, for example, move in level, skew, and curvature Cont and da Fonseca [2002]. A better forecast would likely need an input that tracked the IV level. Without one, the IV update serves to compare IV assumptions on identical stock paths rather than to forecast IV.

Those comparisons pointed to the stock forecast as the main source of option forecast error. Repeating the option forecasts with the stock paths that actually occurred cut option errors 3.8- to 5.4-fold on the same options and dates (Supplementary Table S22). The median stock forecasts from JumpHMM nearly matched a forecast of no price change (Table 4), because the drift we imposed on JumpHMM was small. That drift was an average log return of 10% a year, about 0.2% over five trading days. The simulated five-day log return had a standard deviation near 4%, about twenty times larger. The median simulated price therefore rose by an average of only 0.16–0.27% from the starting price (Supplementary Table S27), so its errors nearly matched those of the no-change forecast. Expected returns are small relative to short-horizon return variation, and even a constant expected return can be estimated precisely only from long spans of data Merton [1980]. Regressions that predict the stock market’s excess return have also rarely beaten its historical average out of sample Welch and Goyal [2008]. We also compared JumpHMM with two simpler stock models.

One of them, the direction-predicting model, forecast drift from recent stock and market returns, and it behaved the same way. Tuned on 2019–2024 data, it forecast best with its drift set to zero (Supplementary Table S30). Starting JumpHMM in the hidden state implied by recent returns did not materially improve five-day forecasts either (Supplementary Table S29). The model’s switching between states largely erased the influence of the starting state within a few days.

The other simpler model, the adaptive-volatility model, scaled its forecast ranges by recent volatility, estimated as an exponentially weighted moving average of recent squared returns. It helped LLY but not GS (Table 4). Volatility, unlike direction, persists enough to be forecast from recent returns [Cont \[2001\]](#), [Andersen and Bollerslev \[1998\]](#). In both test periods, LLY’s volatility also stayed above JumpHMM’s level. Each JumpHMM forecast started from the model’s long-run state probabilities, so the width of its forecasts stayed at the volatility of its 2014–2024 fit. The standard deviation of LLY’s daily returns was 1.5 times that level in 2025 and 1.3 times in August and September 2026 (Supplementary Table S27). The adaptive-volatility estimate tracked those levels and widened LLY’s forecast ranges toward the observed spread of outcomes. The continuous ranked probability score (CRPS) rewards forecast distributions concentrated near the observed outcome. The wider ranges improved LLY’s CRPS in both periods, because LLY’s outcomes spread more widely than JumpHMM’s ranges allowed. Even so, the adaptive-volatility model’s 90% ranges contained fewer than 90% of LLY’s 2025 outcomes (Table 4). In 2025, GS’s daily volatility was within 10% of the JumpHMM level, so the adaptive-volatility model changed GS’s score little (Supplementary Table S27). In August and September 2026, the standard deviation of GS’s daily returns was 1.40% (Supplementary Table S27). This was below both the 1.80% JumpHMM level and the adaptive-volatility estimate, which April–July returns had raised to an average of 2.26%. The 90% ranges of both models already contained every 2026 GS outcome (Table 4). The adaptive-volatility model’s wider ranges therefore made its forecasts less precise without making them more reliable, and the CRPS penalizes that trade [Gneiting et al. \[2007\]](#). The two tickers therefore favor widening JumpHMM’s forecast ranges only when a ticker’s volatility stays above the model’s level, as LLY’s did. Recent volatility alone was not a reliable signal, because GS’s April–July returns overstated its volatility in August and September. Neither the adaptive-volatility model nor the direction-predicting model beat JumpHMM consistently across tickers and periods, so we kept JumpHMM as the example stock model and reported both as comparisons.

Two further problems concern the simulated prices themselves. The first was that the binomial tree prices each option on its own, so nothing forces prices to be consistent across strikes. Some GS prices violated no-arbitrage conditions across strikes, even when IV was set directly from the fitted surface (Supplementary Table S15). For a strategy that holds several options, those inconsistencies matter because decisions depend on relative prices as well as the value of each position. Methods that simulate IV surfaces under no-arbitrage constraints offer a starting point for removing them [Cont and Vuletić \[2023\]](#). Those constraints apply to European options, so American prices from the tree would still need their own checks before simulated prices replace market data. The second problem lay in the fitted surfaces, whose errors on some dates traced partly to scheduled earnings reports. The neural surfaces, which allow more flexible shapes, fitted IV more closely than the parametric surface across all observations (Table 1). Yet on May 11, one of the dates used for fitting, they overpredicted near-the-money IV for MSFT and LLY. The surface fitted on 68 trading days through July 31 made a related error on later dates. For LLY, its daily errors showed that the overprediction began after a scheduled earnings report. The surface underpredicted LLY’s IV by 17.90 volatility points on August 4, the trading day before the August 5 report. It then overpredicted LLY’s IV by 2.04 to 8.07 points on every observed day from August 6 through September 4 (Supplementary Table S27). Option prices have long shown this pattern, with IV rising before an anticipated announcement and falling after it [Patell and Wolfson \[1979\]](#), [Dubinsky et al. \[2019\]](#). Because each ticker’s fitted IV level averaged over the fitting period, one level could not represent IV both before and after a report. For GS, the July 14 report lay inside the fitting period, and the next report came after the test period. The GS errors on later dates ranged from 3.07 points below to 3.59 points above observed IV. Averaged over the five observed sessions before and after each ticker’s latest report, the surface’s error shifted by 3.36 points for GS, compared with 16.45 points for LLY (Supplementary Table S27). The May 11 errors fit the same explanation. The two tickers whose IV the surfaces overpredicted, MSFT and LLY, reported on April 29 and April 30, after ten of the fifteen fitting days (Supplementary Table S5). Adding the time to scheduled earnings reports as a surface input reduced error when surfaces fitted on earlier April dates were tested on April 23 and 24 (Table 2). Refitting the July surfaces with these earnings inputs cut LLY’s overprediction after its report from 6.17 to 3.85 points, with both

values averaged across three training seeds (Supplementary Table S28). That reduction fell short of the halving that we had set in advance as the criterion for supporting the earnings explanation. Report timing therefore explained part of LLY’s error but not all of it. The remainder is consistent with each sector’s surface applying one earnings response to all its tickers, whose IV moved by different amounts around their reports. Both problems also shaped the forecast tests. Rescaling the target to the IV observed on each forecast date removed the error in the starting IV level but left the inconsistencies across strikes in place. Pricing each option with the IV that Alpaca, the data vendor, reported on the forecast’s end date reduced errors more than using the realized stock paths did. That check, however, used information from the later date (Supplementary Table S24). The tests therefore separated four requirements that a synthetic option market must meet: accurate IV surfaces, accurate stock forecasts, a pricing model that matches market prices given the right IV, and prices consistent across strikes.

The data were the main limitation. All option quotes came from Alpaca’s free indicative feed, which is derived from exchange quotes. Our price errors therefore measured agreement with Alpaca’s quotes, not with prices at which trades could execute. The download times also did not tie stock and option prices to the same moment. The observation windows were short. The surface comparisons used fifteen daily snapshots, and the option forecasts covered 23 trading days. Most networks in the tests on later dates were also trained with a single random seed. Overlapping forecast periods and shared market moves further reduced the independent information in these tests. Our daily collection saved only expirations near a fixed ladder of maturities, so the one-month options we first selected had no quotes five trading days later (Supplementary Table S20). The shorter-dated options that replaced them could not validate the one-month GS and LLY examples. Several conclusions rest on thin evidence. We proposed the adaptive-volatility and direction-predicting models after seeing JumpHMM’s August and September forecast misses. The earnings explanation rests on a few reports for three tickers. Some modeling choices also went unchecked. We did not test the cap we placed on JumpHMM’s daily returns against the largest real stock moves. The IV update’s parameters were set by assumption rather than estimated from data. Two optional features in the code, which would let the IV level depend on JumpHMM’s current hidden state and on its visits to extreme-return states, stayed switched off. The present results therefore support controlled comparisons of IV assumptions and the specific forecasts reported here, not trading use. Complete daily histories of the same options, collected across different market conditions, would allow a repeat of the forecast tests on one-month options and a test of the switched-off features.

5 Conclusion

In this study, we built a simulator that values American options along stock paths from a separately chosen stock model, here the jump hidden Markov model JumpHMM. On every simulated date, the simulator moves each option’s implied variance partway toward a target predicted by a neural surface fitted to market quotes. This update borrows the mean-reverting form of the Heston model’s variance equation and adds random shocks. A binomial tree then converts the resulting IV into the option’s price. More flexible surfaces, fitted separately to smaller groups of tickers, matched the fitting data more closely, but their accuracy on later dates was uneven. Part of that unevenness traced to scheduled earnings reports, which a surface fitted over a fixed window could not follow. Repricing identical stock paths under different IV updates changed option values before expiration and the outcome of closing positions early, while payoffs at expiration stayed the same. Linking the random shocks to stock returns raised the worst losses of short puts and lowered those of short calls. In forecasts of later option prices, the IV update with random shocks linked to stock returns showed no consistent advantage over holding IV fixed. Repeating the forecasts with the stock paths that actually occurred reduced option errors, which pointed to the stock forecast as the main source of error. In stock forecasts for 2025 and for August and September 2026, JumpHMM, an adaptive-volatility model, and a direction-predicting model all predicted prices about as accurately as assuming no change. The adaptive-volatility model improved the predicted range of stock prices for LLY in both periods but not for GS. Tuning on 2019–2024 data found no benefit from predicting direction with recent stock and market returns, so the direction-predicting model, which adds a drift to the adaptive-volatility model, gave the same forecasts. The simulator therefore supports reproducible comparisons of IV and stock assumptions, but it did not forecast better than simpler alternatives. Saved observations, fitted models, simulation outputs, and scoring code make every comparison reviewable. With complete option histories and prices made consistent across strikes, the same

approach could supply realistic option prices for testing trading and hedging systems on hypothetical market paths.

Data and Code Availability

All data, code, and saved results for this study are available at https://github.com/varnerlab/heston_implied_volatility_model. The repository contains the daily option-chain snapshots from April 14 through September 4, 2026, the daily stock prices, the earnings calendar, and the pretrained JumpHMM model. It also contains the scripts that fit the IV surfaces, run the simulations and tests, and summarize their results, together with the saved outputs and logs. The repository's README.md gives the command for each experiment, and SETUP.md lists the setup steps. The option quotes come from Alpaca's free indicative feed, a modified version of the exchange feed, so they may differ from exchange quotes [Alpaca Markets \[2026b\]](#). The code is released under the MIT License.

A Interpretation of the IV Factor

A continuous-time square-root process motivated the Euler update in (12). For a fixed target, the process is given by:

$$dv_{a,t} = \kappa(\bar{v}_{a,t} - v_{a,t})dt + \sigma_v \sqrt{v_{a,t}} dW_{a,t}, \quad (18)$$

where contract a indexes ticker, strike, and expiration, and the target $\bar{v}_{a,t}$ from (7) changes with current moneyness and calendar DTE. The stationary mean of this process, when it exists, equals the fixed target $\bar{v}_a$. The simulation departed from this setting in two ways. The target moved every trading day, and the floor in (12) modified the process. The stationary mean therefore explains why each factor reverts toward its target, but it does not give the simulated distribution.

B Calibration Details

The [source repository](#) provides the experiment drivers and reproduction instructions. Its data manifest records each file’s SHA-256 hash and filtered row count. The saved ablation outputs include the pilot constants, path-level prices, numerical checks, and copies of the source code, so each reported comparison can be traced to its inputs.

Each calibration snapshot had a label, a capture timestamp, and an underlying-session date, and these did not always coincide (Table S1). The distinction matters because the holdout tests split dates in different ways. All dates are in 2026. For example, the snapshot for the May 11 underlying session was captured on May 12. The first snapshot contained 23 tickers, and each later snapshot contained 31.

Table S1: Labels, capture dates, and underlying-session dates of the calibration snapshots. The April earnings holdout split dates by snapshot label. The May 11 single-date holdout used the underlying-session date. The first snapshot is labeled April 14, but its underlying close was from April 13. Rows counts the filtered observations from each snapshot.

Snapshot label	Capture date	Underlying session	Rows
04-14-2026	2026-04-14	2026-04-13	18,250
04-15-2026	2026-04-15	2026-04-15	17,711

05-06-2026	2026-05-07	2026-05-06	17,293
05-08-2026	2026-05-08	2026-05-08	12,293
05-11-2026	2026-05-12	2026-05-11	14,442

Table S2: Sector assignment of the 31 tickers across the fifteen snapshots. Counts are the filtered observations used in fitting.

Sector	Observations	Tickers
ETF	102,738	IWM, QQQ, SPY
Technology	68,334	AAPL, AMD, AVGO, GOOG, INTC, META, MSFT, MU, NVDA, QCOM
Healthcare	26,387	ABBV, AMGN, BMY, JNJ, LLY, MRNA, PFE, UNH
Financials	17,938	BAC, GS, JPM, WFC
Retail	11,320	TGT, UPS, WMT
Energy	7,832	CVX, OXY, XOM

Table S3: In-sample IV RMSE of the parametric, global neural, and sector neural surfaces by sector. Errors are in volatility percentage points. The sector network improved on the global neural network in every group, but technology and healthcare kept the largest errors.

Sector	Parametric	Global NN	Sector NN	Observations
ETF	10.54	8.69	6.10	102,738
Financials	9.05	7.79	6.70	17,938
Energy	9.36	8.24	7.88	7,832
Retail	11.73	10.23	9.50	11,320
Healthcare	13.49	12.71	12.53	26,387
Technology	15.58	15.31	14.47	68,334

Table S4: In-sample IV RMSE of the sector and per-ticker networks for the 29 qualified tickers. Rows are sorted by the reduction from the sector network to the ticker's own network. A positive reduction means the ticker's own network fitted better than its sector network. The final rows count the tickers that improved and worsened. Two tickers, BMY and PFE, kept their sector surfaces. Combining per-ticker networks with these sector fallbacks reduced pooled RMSE from 10.24 to 9.73 volatility percentage points (Table 1).

Ticker	Observations	Sector NN	Per-ticker NN	Reduction
JNJ	2,190	11.14	7.17	3.97
MRNA	2,851	17.49	13.74	3.76
AAPL	6,594	14.30	12.59	1.70
INTC	3,417	17.78	16.29	1.49
AMGN	3,383	13.36	12.14	1.21
MU	6,619	18.45	17.26	1.19
NVDA	5,805	10.14	9.15	0.99
AVGO	9,470	9.94	9.28	0.67
UNH	3,760	10.39	9.77	0.63
AMD	4,566	17.74	17.13	0.61
MSFT	10,129	14.33	13.79	0.54
GOOG	4,433	9.57	9.05	0.53
QCOM	3,375	21.46	20.99	0.47
GS	8,772	5.40	4.98	0.42
SPY	42,224	6.02	5.72	0.30
IWM	21,368	6.11	5.82	0.29
LLY	8,531	11.35	11.06	0.29
META	13,926	13.72	13.45	0.26
ABBV	2,525	9.13	8.95	0.18
QQQ	39,146	6.17	6.08	0.09
TGT	3,957	9.54	9.48	0.06
BAC	2,399	9.47	9.53	-0.06
XOM	2,820	7.31	7.41	-0.10
CVX	2,453	7.70	7.81	-0.11
OXY	2,559	8.60	8.81	-0.20
WFC	3,047	7.94	8.17	-0.24
UPS	3,526	11.44	11.68	-0.25
WMT	3,837	7.23	7.52	-0.29
JPM	3,720	6.18	6.65	-0.47
Tickers with lower per-ticker RMSE				21
Tickers with higher per-ticker RMSE				8

Table S5: Observed and predicted mean IV near the money in the May 11 smile panels (Fig. 1). Each row averages the plotted calls and puts with $0.98 \leq K/S \leq 1.02$ at the indicated calendar days to expiry (DTE). Predictions use the saved fifteen-date fit, evaluated at each observed contract. Observed and predicted IV are percentages. Bias is the mean per-ticker predicted IV minus observed IV, in percentage points. The NVDA subset contains only two observations. According to the public earnings calendar, GS, MSFT, and LLY reported on April 13, April 29, and April 30, 2026, respectively, all within the calibration window.

Ticker	DTE	N	Observed IV	Predicted IV	Bias
SPY	7	52	13.57	13.75	+0.18
NVDA	7	2	38.65	34.02	-4.62
MSFT	9	14	28.47	37.92	+9.45
LLY	11	20	38.59	46.49	+7.90
GS	11	24	32.06	31.74	-0.32
AVGO	9	14	49.08	43.72	-5.37

Table S6: Median half-spreads and American-option pricing errors on May 11 for the contracts plotted in Fig. 2. Dollar values are medians across the plotted contracts. Each error is the absolute difference between the tree price and the market mid. The per-ticker column used a per-ticker surface where the ticker qualified and a sector surface otherwise. Inside spread is the share of contracts whose absolute per-ticker error was at most their half-spread. The market-IV reference passed each contract’s reported IV to the same 200-step CRR tree.

Ticker	DTE	N	Median half-spread	Median per-ticker error	Inside spread	Median market-IV error
SPY	7	176	\$0.03	\$0.12	33%	\$0.01
NVDA	7	34	\$0.04	\$0.13	35%	\$0.12
LLY	11	156	\$2.98	\$4.01	30%	\$0.67
GS	11	145	\$1.56	\$0.46	88%	\$0.12

Table S7: Five best and five worst tickers by in-sample IV RMSE under the sector networks. Errors are in volatility percentage points.

Rank	Ticker	Observations	RMSE	Sector
<i>Best five</i>				
1	GS	8,772	5.40	Financials
2	SPY	42,224	6.02	ETF
3	IWM	21,368	6.11	ETF
4	QQQ	39,146	6.17	ETF
5	JPM	3,720	6.18	Financials
<i>Worst five</i>				
27	PFE	1,300	17.66	Healthcare
28	AMD	4,566	17.74	Technology
29	INTC	3,417	17.78	Technology
30	MU	6,619	18.45	Technology
31	QCOM	3,375	21.46	Technology

B.1 Single-date holdout

To test transfer to a nearby date, we held out May 11, 2026, and retrained the sector surfaces on the other fourteen dates, standardizing inputs with the training rows alone. Test error exceeded training error only slightly when pooled, but by more in two sectors (Table S8). The pooled gap was 0.68 volatility percentage points, whereas energy and retail had larger gaps. The small pooled gap therefore hid poorer transfer in those sectors. The test used one held-out date and one training seed.

Table S8: Training and test RMSE of the sector networks with May 11, 2026, held out. The networks were fitted on the other fourteen dates and tested on the 14,442 observations from May 11. Values and test-minus-train gaps are in volatility percentage points.

Sector	Train	Test	Gap
ETF	6.12	5.87	−0.25
Financials	6.72	6.32	−0.40
Healthcare	12.58	12.00	−0.58
Technology	14.45	15.04	+0.58
Energy	7.74	9.97	+2.23
Retail	9.21	13.17	+3.96
Pooled	10.21	10.89	+0.68

C Earnings-Holdout Ticker Results

We broke the April earnings-holdout result down by technology ticker and found that the earnings inputs lowered test error for some tickers and raised it for others (Table S9). The two-input and four-input models used the same training and test observations. Several tickers with a peer earnings date near the holdout had lower error with the earnings inputs, but AVGO, NVDA, and INTC had higher errors. Because the ticker and peer distances entered together, the comparison could not separate their contributions. Calendar distance also carries no information about the sign or size of an earnings surprise.

Table S9: Test RMSE of the technology tickers in the April earnings holdout under the pooled two-input model (A) and the earnings-aware model (C). The inputs e and e^{peer} are the median signed ticker distance and the minimum peer distance to an earnings date, in days. Error differences are in volatility percentage points.

Ticker	e	e^{peer}	A: pooled	C: event inputs	Difference
QCOM	+5	1	41.66	37.59	−4.07
AMD	+11	1	40.07	36.50	−3.57
META	+5	1	14.32	10.73	−3.59
MSFT	+5	1	14.00	10.73	−3.28
GOOG	+5	1	9.87	7.90	−1.97
MU	−30	1	16.95	15.59	−1.36
AAPL	+6	1	10.42	10.34	−0.08
AVGO	+30	1	12.58	12.83	+0.24
NVDA	+26	1	9.43	10.47	+1.05
INTC	−1	5	33.17	35.94	+2.77

D Scenario Statistics and Greeks

The GS and LLY illustrations shared one simulation design (Table S10). For GS, the seller usually kept the full premium but faced large losses in the lower tail (Table S11). The premium-retained interval is a two-sided 95% Wilson interval for the fraction of paths that expired out of the money. It measures only the Monte Carlo sampling error in that fraction.

Table S10: Simulation settings shared by the GS and LLY illustrations.

Setting	Value
Simulation paths	1,000
Random seed	20260429
Horizon	April 28–May 29, 2026
Calendar days	31
Trading transitions	22
Annual mean-growth prior	10%
Mean-reversion rate κ	15
Factor volatility σ_v	0.5
Return–factor coupling ρ	−0.6
Risk-free rate r	4.25%
Dividend yield q	0
Leisen–Reimer depth	201

Table S11: Entry prices and short-position outcomes for the GS put and call over 1,000 simulated paths from April 28 to May 29, 2026. The horizon had 31 calendar days and 22 trading-day steps. Option values and P&L are in dollars per share.

Statistic	Short put	Short call
Initial spot	926.38	
Strike	890.00	970.00
Market delta	−0.295	+0.328
Market IV	31.2%	28.9%
Market mid	16.51	16.09
Model entry value	17.26	16.07
Model value minus market mid	0.75	−0.02
Mean P&L	4.30	−2.19
Monte Carlo SE of mean	0.89	1.23
Median P&L	16.51	16.09
Standard deviation	28.01	38.87
5% quantile	−58.96	−86.18
5% expected shortfall	−92.15	−130.77
Premium retained	74.0%	67.7%
Wilson 95% interval	71.2–76.6%	64.7–70.5%
Delta-heuristic premium retained	70.5%	67.2%
Simulated minus heuristic	+3.5 pp	+0.5 pp

We calculated Greeks along each path by central finite differences on the same Leisen–Reimer tree that supplied the base price (Algorithm S1). For GS, delta approached ± 1 on paths heading toward exercise, gamma concentrated near the strike, and Vega declined toward zero (Fig. S1). The figures use the long-option sign convention, so a short position’s Greeks have the opposite sign.

Algorithm S1 Greeks by central finite differences along each path

Require: State (S, σ, τ) with calendar DTE τ ; contract (K, r) ; LR tree steps N_{LR} ; relative spot bump h_S ; absolute IV bump h_σ .

Ensure: Δ , Γ , and Vega.

- 1: $T_{\text{yr}} \leftarrow \tau/365$.
 - 2: $P_+^S \leftarrow \text{LR}(S(1+h_S), K, \sigma, T_{\text{yr}}, r)$ and $P_-^S \leftarrow \text{LR}(S(1-h_S), K, \sigma, T_{\text{yr}}, r)$.
 - 3: $P_0^S \leftarrow \text{LR}(S, K, \sigma, T_{\text{yr}}, r)$.
 - 4: $P_+^\sigma \leftarrow \text{LR}(S, K, \sigma+h_\sigma, T_{\text{yr}}, r)$ and $P_-^\sigma \leftarrow \text{LR}(S, K, \sigma-h_\sigma, T_{\text{yr}}, r)$.
 - 5: $\Delta \leftarrow (P_+^S - P_-^S)/(2h_S S)$.
 - 6: $\Gamma \leftarrow (P_+^S - 2P_0^S + P_-^S)/(h_S S)^2$.
 - 7: $\text{Vega} \leftarrow 0.01(P_+^\sigma - P_-^\sigma)/(2h_\sigma)$.
 - 8: **return** $(\Delta, \Gamma, \text{Vega})$.
-

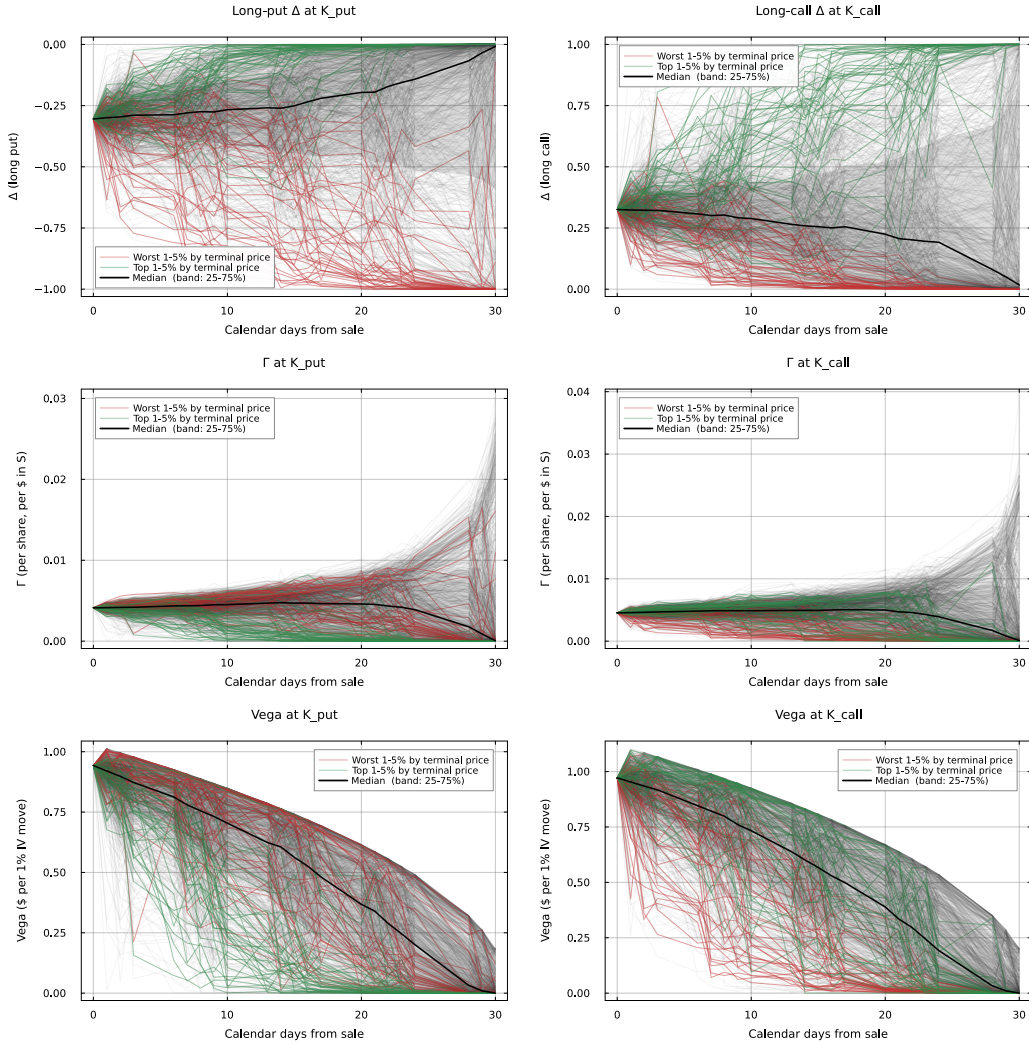

Figure S1: Simulated evolution of GS long-option delta, gamma, and Vega along the stock paths. Sensitivities come from the 201-step Leisen–Reimer tree, with stock-price bumps of 1.5% and IV bumps of 0.005. Vega is in dollars per volatility percentage point.

Table S12: Entry prices and short-position outcomes for the LLY put and call over 1,000 simulated paths from April 28 to May 29, 2026. The horizon had 31 calendar days and 22 trading-day steps. Option values and P&L are in dollars per share.

Statistic	Short put	Short call
Initial spot	873.83	
Strike	825.00	940.00
Market delta	-0.303	+0.309
Market IV	44.4%	44.0%
Market mid	23.30	20.76
Model entry value	21.95	18.96
Model value minus market mid	-1.35	-1.80
Mean P&L	16.39	10.61
Monte Carlo SE of mean	0.63	0.91
Median P&L	23.30	20.76
Standard deviation	19.86	28.66
5% quantile	-27.91	-51.96
5% expected shortfall	-56.84	-94.18
Premium retained	80.7%	79.3%
Wilson 95% interval	78.1–83.0%	76.7–81.7%
Delta-heuristic premium retained	69.7%	69.1%
Simulated minus heuristic	+11.0 pp	+10.2 pp

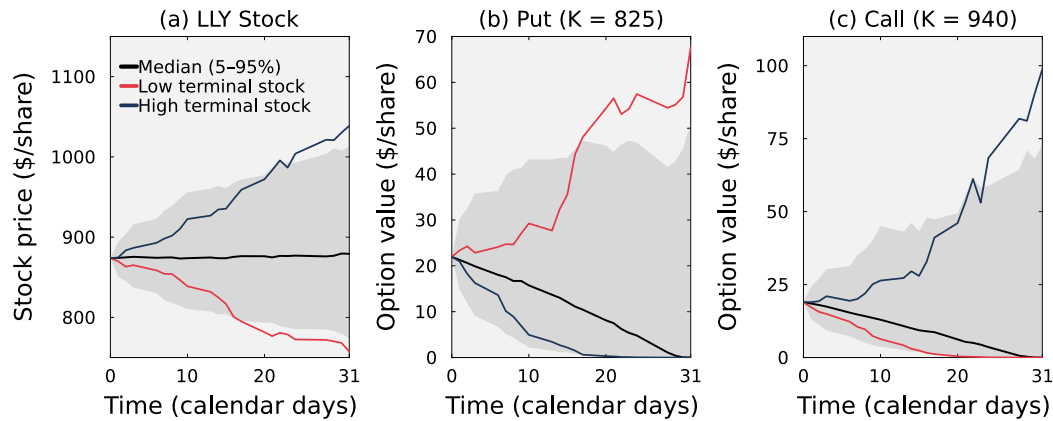

Figure S2: Simulated evolution of LLY stock prices (a), put values (b), and call values (c) along 1,000 paths between April 28 and May 29, 2026. The fitted surfaces included observations from this period, so these paths illustrate the model and are not an out-of-sample forecast. Time is measured in calendar days from April 28. Black curves show pointwise medians, and shading contains the middle 90% of values. Red and blue curves show medians of the paths whose terminal stock price fell in the 1st–5th and 95th–99th percentiles. Option values are in dollars per share and equal a short seller’s cost of buying back the option. Entry premiums were \$23.30 per share for the put and \$20.76 for the call (Supplementary Table S12).

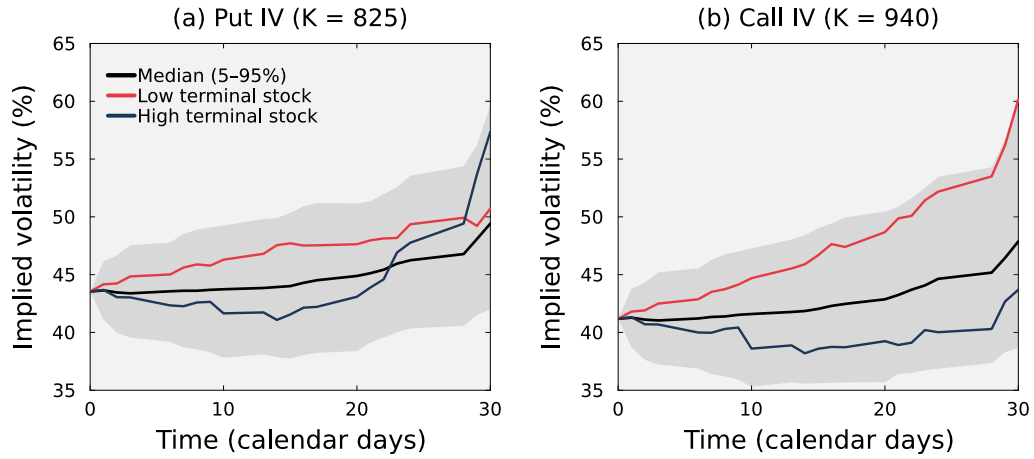

Figure S3: Simulated evolution of annualized IV at the LLY put strike (a) and call strike (b). Both panels express IV as percentages on the same vertical scale. Curves show pointwise medians across all 1,000 paths and within the terminal-stock groups in Supplementary Fig. S2. Shading shows the 5th–95th percentile band. Time is measured in calendar days from April 28, 2026. The curves stop before expiration because the payoff at expiration does not depend on IV.

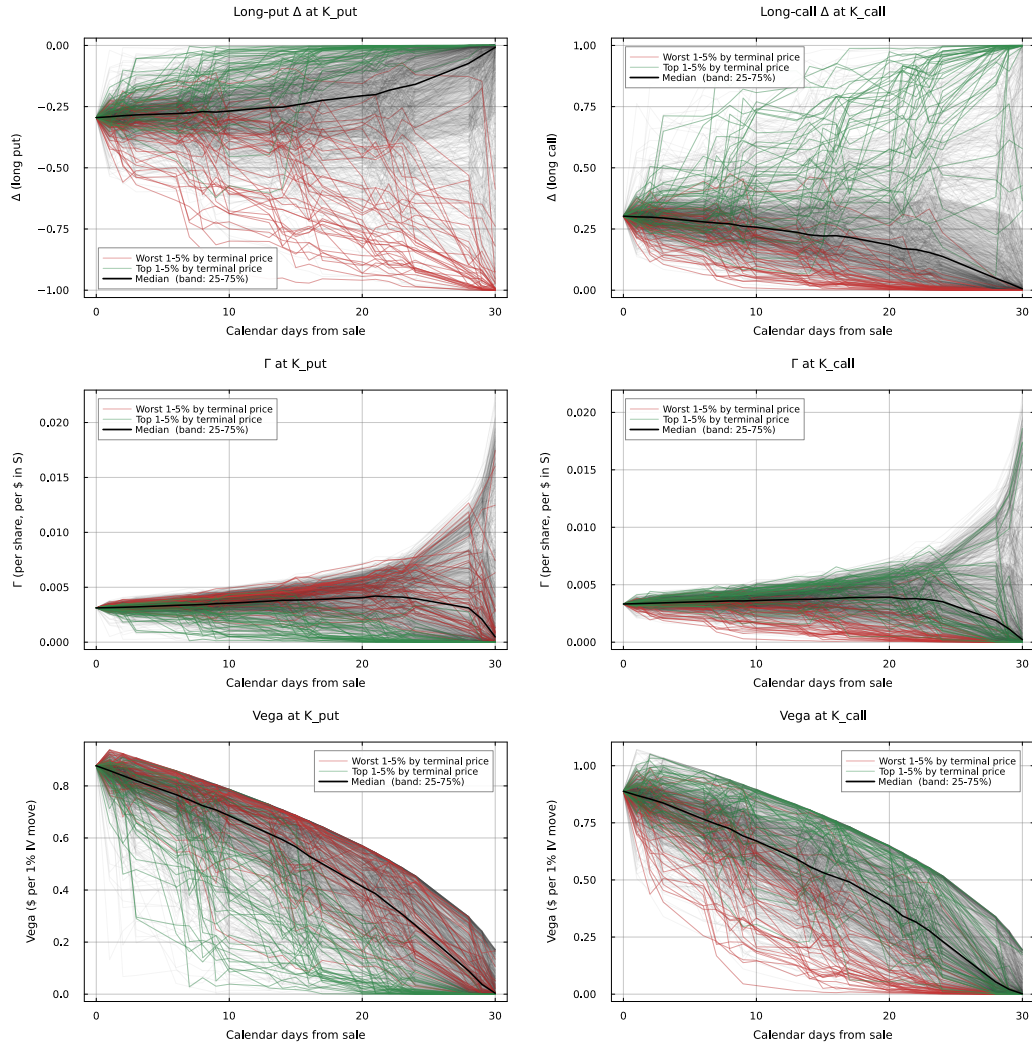

Figure S4: Simulated evolution of LLY long-option delta, gamma, and Vega along the stock paths. Sensitivities come from the 201-step Leisen–Reimer tree. Short-position Greeks have the opposite sign.

E IV Ablation and Strike Audit

At the primary endpoint, ten trading days after entry, we compared the P&L from closing each short position under the five IV variants on shared stock paths (Table S13). The paired standard errors apply to mean differences only, so we reported no interval for expected shortfall. The three evaluation seeds used the same fitted models and pilot constants. We reported them separately to show whether the differences and the numerical checks held across simulations (Table S14).

Table S13: Profit and loss (P&L) from closing short positions after ten trading days, on May 12, 2026, with 17 calendar DTE remaining. Each row uses 3,000 paths. Monetary values are in dollars per share. The columns $\Delta P\&L$ (paired P&L difference) and mean $|\Delta P|$ (mean absolute price difference) compare each variant with the direct surface on identical paths. Parentheses give the paired Monte Carlo standard error of mean $\Delta P\&L$. A more negative 5% expected shortfall ($ES_{5\%}$) means larger losses in the lower tail.

Contract	IV variant	Mean P&L	$ES_{5\%}$	$\Delta P\&L$ (SE)	Mean $ \Delta P $
GS put	Frozen IV	0.67	-63.08	+0.28 (0.01)	0.51

LLY call	Full factor	6.26	-45.18	+2.18 (0.04)	2.41

Table S14: Comparison of the full factor with the direct surface after ten trading days, with numerical diagnostics, for each evaluation seed. Each row uses 1,000 paths. Monetary values are in dollars per share. Mean $|\Delta P|$, mean $\Delta P\&L$, and its paired standard error compare the full factor with the direct surface. Outside is the percentage of path dates before expiration on which strike/spot lay outside the 0.8 to 1.2 range of the calibration data. Floor is the largest percentage of simulated dates on which the factor sat at the variance floor, taken across the five IV variants. Tree change is the largest absolute price change from 201 to 401 tree steps across the five variants. It uses the first twenty paths after ten and twenty trading days.

Contract	Seed	Mean $ \Delta P $	Mean $\Delta P\&L$	Paired SE	Outside (%)	Floor (%)	Tree change (\$)

Because the tree priced each option separately, nothing forced the prices to be consistent across strikes. The strike audit therefore checked necessary conditions for that consistency at 401 tree steps (Table S15). The grid had eleven fixed strikes at the scenario expiration, evaluated at entry and on fifty stock paths after ten and twenty trading days. As the stock moved, some strikes left the moneyness range of the calibration data, so the audit included extrapolated surface values. Each variant and ticker supplied 2,222 bound checks, 2,020 adjacent-strike checks, and 1,818 convexity checks across calls and puts. Violation counts were identical at 201 and 401 steps (Table S16). The saved output lists each test location and violation size.

Table S15: Strike-condition violations larger than \$0.01 per share at 401 tree steps, by ticker and IV variant. Each entry gives violations/tests. The vertical check tests the upper bound on the price difference between options at adjacent strikes. Max reports the largest positive deviation across the four checks, including deviations below the reporting tolerance.

Ticker	Variant	Bounds	Monotonicity	Vertical	Convexity	Max (\$)
GS	Frozen IV	0/2222	0/2020	0/2020	0/1818	0.008

F Details of the Tests on Later Dates

To show how next-date surface error varied over the test period, we summarized the fold errors of the 53 expanding-window splits by test month (Table S17). We reported the July-cutoff surfaces separately because they used a longer training window, the capture audit, recomputed calendar DTE, and a later test period (Table S18).

Table S17: Next-date IV errors of the sector surfaces across the 53 expanding-window folds, by test month. Each fold fitted earlier capture dates and evaluated the next captured date using its observed stock price. The RMSE is in volatility percentage points. Median, minimum, and maximum are taken across the folds in each month. The last row pools all 53 folds.

Test month	Folds	Median RMSE	Minimum	Maximum
April	6	12.72	7.79	17.45
May	17	9.62	8.65	11.30
June	18	10.02	8.55	19.25
July	12	9.76	7.68	10.51
All folds	53	9.92	7.68	19.25

Table S18: Training and held-out IV errors of the July-cutoff sector surfaces, fitted through July 31. Training used 68 underlying sessions. Testing used 23 later sessions from August 4 through September 4. Each RMSE pools observations within the indicated group. Bias is predicted minus observed IV, in percentage points. The last two rows show GS and LLY alone.

Group	Train rows	Test rows	Train RMSE	Test RMSE	Test bias
ETF	503,487	186,987	7.03	6.59	+3.08
Financials	83,005	27,853	7.40	7.81	+2.50
Energy	34,817	10,956	8.15	9.40	+2.45
Retail	50,776	15,096	10.02	11.77	+1.83
Healthcare	126,818	45,472	12.14	12.21	+3.77
Tech	374,635	138,697	14.70	22.91	+14.81
Pooled	1,173,538	425,061	10.79	14.75	+6.88
GS	41,119	14,330	6.78	6.30	+0.88
LLY	39,242	13,753	9.47	9.96	+4.61

Table S19: Data checks for the expanding-window and July-cutoff experiments. The expanding-window rows come from an independent reconstruction of the saved row counts. The July-cutoff rows come from the capture audit. Every excluded file had a retained file for the same ticker and session.

Experiment	Check	Value
Expanding-window folds	Capture dates	58
	Option files	1,790
	Accepted observations	986,492
	Crossed or missing asks	0
	Missing or nonpositive bid or ask sizes	0
July-cutoff surfaces	Downloaded files	2,833
	Files retrieved during trading hours (excluded)	20
	Superseded files (excluded)	0
	Files retained	2,813
	Training observations (68 sessions)	1,173,538
	Test observations (23 sessions)	425,061

Options were chosen at each origin before any later quote was examined, and not every chosen option could be scored. The availability counts therefore separate forecasts whose endpoint fell inside the test window from those with an exact-symbol quote at the endpoint (Table S20). The observed-stock diagnostic also needed a recorded close on every intervening session, which is stricter than having an endpoint quote. It therefore used a smaller subset, the same for every IV variant.

Table S20: Availability of exact-contract outcomes by cohort, ticker, and horizon. Horizons are in trading sessions. Selected counts all origin-selected contracts whose endpoint fell within the fixed window, including endpoints on missing capture dates. Matched counts the selected contracts with an exact-symbol quote at the endpoint. Full stock path counts selected contracts with all intervening stock observations, whether or not the endpoint option quote was available.

Cohort	Ticker	Horizon	Origins	Selected	Matched	Missing	Full stock path
monthly	GS	1	22	44	34	10	42
monthly	GS	5	18	36	0	36	26

LLY	5	JumpHMM	17	49.83	35.71	70.6
LLY	5	Random walk	17	48.64	34.33	70.6

Table S24: Errors of American-tree prices computed with the IV reported at the endpoint, for matched options with valid reported IV. This diagnostic uses information from the endpoint, so it is not a forecast. The MAE is in dollars per share. Inside-spread frequencies compare each price with Alpaca's indicative bid and ask.

Cohort	Ticker	Horizon	Dates	Quotes	MAE	Inside spread (%)
monthly	GS	1	17	34	0.24	97.1
monthly	LLY	1	17	34	0.46	100.0
short	GS	1	21	42	0.16	100.0
short	GS	5	17	34	0.14	100.0
short	LLY	1	21	41	0.32	100.0
short	LLY	5	17	30	0.34	100.0

Table S25: Five-session option errors under mean and median point forecasts for the shorter-maturity cohort. Mean MAE and Mean RMSE score the simulated mean, and Median MAE scores the median. The prespecified comparison scores the mean, and the median is an added summary. All errors are in dollars per share and use the same date-weighted options as Table 3.

Stock	IV variant	Mean MAE	Median MAE	Mean RMSE
GS	Frozen IV	4.21	2.48	5.06
GS	Direct surface	4.86	2.62	5.62
GS	Mean reversion	4.26	2.50	5.10
GS	Uncoupled factor	4.24	2.48	5.08
GS	Full factor	4.19	2.48	4.99
LLY	Frozen IV	11.62	11.78	15.00
LLY	Direct surface	11.62	11.59	14.74
LLY	Mean reversion	11.62	11.77	14.98
LLY	Uncoupled factor	11.61	11.80	14.97
LLY	Full factor	11.59	11.79	14.92

Before interpreting small differences between IV variants, we checked that the forecast prices were reproducible and numerically accurate. Recomputing prices from the saved stock and variance paths reproduced the forecast means, quantiles, and CRPS. Increasing the tree from 201 to 401 steps changed sampled prices by at most \$0.0026 per share (Table S26). At the first origin for each ticker, the paired Monte Carlo standard errors of the mean price difference between the full factor and frozen IV ranged from \$0.041 to \$0.061 across the four shorter-maturity options at five sessions (Table S26). These standard errors measure simulation precision for a single price difference, not

variation across market dates. The small average MAE reductions therefore do not show that the full factor forecasts better (Table 3). In the observed-stock diagnostic, frozen IV, the direct surface, and deterministic mean reversion each gave a single price once the stock path was fixed, so their central intervals had zero width. The stochastic factors' intervals reflected IV uncertainty alone, so their coverage measures something different from the coverage of the joint forecasts (Table S22). The saved score files include both cohorts, every horizon with outcomes, all five IV variants, and the date-level errors.

Table S26: Numerical checks of the forecast prices at the first origin, August 4, 2026. Sampled prices repeat the tree calculation with 201 and 401 steps for both cohorts, all five IV variants, calls and puts, and the first ten paths. Price changes and standard errors are in dollars per share. Paired Monte Carlo SE is the standard error of the mean price difference between the full factor and frozen IV across 1,000 paths. It applies to the shorter-maturity options at the five-session endpoint.

Check	GS	LLY
Sampled prices, 201 and 401 steps	300	300
Largest price change, 201 to 401 steps	0.0022	0.0026
Paired Monte Carlo SE, five-session put	0.041	0.052
Paired Monte Carlo SE, five-session call	0.051	0.061

Four quantities explain the forecast outcomes: IV-factor persistence, central stock drift, stock volatility, and surface bias (Table S27). With $\kappa = 15$ and $\Delta t = 1/252$, the Euler update in (12) retained a fraction $1 - \kappa\Delta t \approx 0.94$ of a factor's deterministic gap to a fixed target at each session. This retention gave a half-life of 11.3 sessions, so the update closed 26.4% of the gap after five sessions and 45.9% after ten. The five-session rows used the seventeen scored origins per ticker and the matched contracts in Table 3. Their IV changes compared simulated IV five sessions after origin with the observed origin IV, averaging over paths and then contracts. The one-session volatility rows used the stock-benchmark origins in Table 4. Realized values were sample standard deviations of the observed one-session log returns, and EWMA values averaged the adaptive-volatility model's origin estimates. The GS EWMA estimate began from its 2014–2024 sample variance and rose through the April–July 2026 returns before the first August origin. The surface-bias rows break the held-out ticker bias in Table S18 down by underlying session. The report rows average each ticker's daily bias over the five observed sessions before and after its latest report. They exclude the report day, weight each session by its number of observations, and use training and held-out days alike. The public earnings calendar dated LLY's report on August 5, 2026, after the training cutoff, and GS's on July 14, 2026, inside the training window.

Table S27: Diagnostics of IV-factor persistence, central stock drift, stock volatility, and surface bias. Five-session rows average the scored shorter-maturity origins and matched options. Changes in IV are in volatility percentage points relative to the observed origin IV. One-session stock rows use the 2025 and August–September 2026 stock-benchmark origins. Surface bias is predicted minus observed IV for the July-cutoff sector surface, in volatility percentage points. Earnings reports fell on August 5, 2026, for LLY and July 14, 2026, for GS. Report rows exclude the report day.

Quantity	GS	LLY
<i>Five-session forecasts, shorter-maturity cohort</i>		
JumpHMM median price change (%)	0.27	0.16
JumpHMM log-return standard deviation (%)	3.98	3.76
Full-factor mean IV minus origin IV (points)	0.30	0.18
Full-factor mean absolute IV change (points)	2.49	2.47
Direct-surface mean absolute IV change (points)	5.50	4.12
<i>One-session stock return standard deviation (%)</i>		
JumpHMM pilot	1.80	1.70
Realized, 2025	1.97	2.57
EWMA at origin, 2025	1.94	2.52
Realized, August–September 2026	1.40	2.19
EWMA at origin, August–September 2026	2.26	2.14
<i>Held-out July-cutoff surface bias (points)</i>		
August 4	−3.07	−17.90
August 5	−0.96	−0.53
August 6–September 4, mean	1.20	6.17
August 6–September 4, range	−0.68 to 3.59	2.04 to 8.07
<i>Surface bias around each ticker’s latest report (points)</i>		
Five observed sessions before	−3.93	−11.26
Five observed sessions after	−0.57	5.19
Change	3.36	16.45

The timing of LLY’s report, after the training cutoff, suggested an earnings explanation for its held-out bias. We tested this explanation by refitting the July surfaces with the two earnings inputs used in the April holdout (Table S28). A protocol written before fitting kept the two-input surfaces’ training and test rows, architecture, and training schedule. It fitted seeds 42, 43, and 44 for both versions, with the underlying session as the observation date. The protocol set two conditions for calling the explanation supported. The earnings inputs had to at least halve LLY’s mean absolute bias from August 6 through September 4, and every earnings-aware seed had to fall below every two-input seed. The protocol called the explanation not supported if the inputs did not reduce the bias. The earnings inputs reduced that bias from 6.17 to 3.85 volatility points on average, and every earnings-aware seed fell below every two-input seed. The 38% reduction fell short of half, so the prespecified verdict was partial. The inputs also reduced LLY’s underprediction on August 4 from 17.90 to 12.86 points and pooled held-out RMSE from 14.75 to 13.94 points. The held-out RMSE for GS changed by less than 0.1 point. The two-input refits varied by less than 0.05 points across seeds in every reported quantity, so these differences exceed seed variation. Each sector network shares one earnings response across its tickers, so the refit could represent a typical report effect but not one sized to each ticker. Across their latest reports, LLY’s bias shifted about five times as much as GS’s (Table S27).

Table S28: Bias and RMSE of the July-cutoff sector surfaces refitted with and without earnings inputs. Values are means across training seeds 42, 43, and 44, with the seed range in parentheses. Bias is predicted minus observed IV. Bias and RMSE are in volatility percentage points. The two-input fit with seed 42 is the published surface. The earnings inputs are the signed calendar days to the ticker’s nearest report and the days to the nearest same-sector peer report, each clipped at 30. For ETFs, both inputs are the days to the nearest report among all non-ETF stocks.

Quantity	Two inputs	With earnings inputs
LLY bias, August 6–September 4	6.17 (6.16 to 6.18)	3.85 (3.54 to 4.05)
LLY bias, August 4	−17.90 (−17.92 to −17.88)	−12.86 (−13.04 to −12.73)
GS bias, August 6–September 4	1.21 (1.20 to 1.22)	0.51 (0.46 to 0.57)
LLY held-out RMSE	9.96 (9.96 to 9.97)	8.50 (8.36 to 8.59)
GS held-out RMSE	6.31 (6.30 to 6.31)	6.37 (6.31 to 6.41)
Pooled held-out RMSE	14.75 (14.75 to 14.76)	13.94 (13.87 to 14.00)
Pooled training RMSE	10.79 (10.78 to 10.79)	10.35 (10.29 to 10.39)

G Stock Forecast Evaluation

Before comparing stock forecast methods, we checked the saved JumpHMM forecasts in two ways. The first check concerned how returns were scaled. The saved GS and LLY models used daily steps of $1/252$ year and annualized excess log returns. Reconstructing the first-origin forecasts with this scaling reproduced the saved stock means at both one and five sessions. The second check concerned the starting hidden state, which the original forecasts drew from the stationary distribution without using recent returns. In this initialization check, we instead inferred the current hidden state from the available daily returns and advanced it before generating the first future return. The inference tracked both the return state and the number of forced tail-state emissions left in a jump episode. Poisson durations kept all but at most 10^{-12} of the probability, with the remainder assigned to the final duration. A missing day advanced the hidden-state distribution without an observation likelihood. A return accumulated over several days was never treated as a daily observation. We removed the fixed pilot growth shift from observed annualized returns before computing likelihoods, to match the simulated observation model. We compared this conditional start with the original start on the same 2026 endpoints (Table S29). Both used three 10,000-path runs, with seeds separate from the four-method benchmark. The fitted transitions mixed the hidden states within a few sessions, so the conditional start had little effect on five-session central forecasts. Other exploratory checks, including a fixed 20-return volatility adjustment and Gaussian random walks, are kept in the saved experiment outputs.

Table S29: Stock forecast errors from the original starting state and from a starting state conditioned on past returns, on identical 2026 endpoints. Each ticker has 21 one-session and 17 five-session origins. The MAE scores the forecast median. Errors are in dollars per share and average three 10,000-path runs. Filtered denotes initialization from available past returns, including inference of remaining jump duration.

Stock	Horizon	Original MAE	Filtered MAE	Original CRPS	Filtered CRPS
GS	1	10.64	10.79	7.99	8.44
GS	5	16.28	16.36	12.99	13.21
LLY	1	19.10	19.08	14.73	14.62
LLY	5	49.58	49.40	35.69	35.35

The benchmark comparison kept JumpHMM’s fitted parameters and truncated emissions and tested the adaptive-volatility and direction-predicting models against it. We chose the settings of both models on earlier data only. For each annual validation block from 2019 through 2024, regression training responses ended before the validation year and validation endpoints remained within it. The EWMA variance began with the sample variance of the first sixty training daily returns and then updated using only returns observed by each origin. Decay selection minimized

$\frac{1}{2}[\log(ha_t) + y_{t,h}^2/(ha_t)]$, where $y_{t,h}$ was the observed cumulative log return over h sessions. We first averaged this loss within each ticker, validation year, and horizon, then gave the resulting groups equal weight. With the selected decay, the direction-predicting model's regression fitted the next daily return divided by origin volatility. Its four features were the stock's last daily return, its last five- and twenty-return sums, and SPY's last five-return sum. Return sums were divided by the square root of the window length and by the same asset's EWMA volatility at the origin, so SPY's feature used SPY's volatility. Each feature column was then divided by its training root mean square. The ridge objective was the mean squared normalized one-session error plus the penalty times the squared coefficient norm, with no intercept. Penalty selection used $(y_{t,h} - h\hat{\mu}_t)^2/(ha_t)$, with the same group weighting as decay selection. The zero-drift limit had the lowest validation loss and set all four coefficients to zero for both tickers (Table S30). The two selection losses measure different things, so their magnitudes cannot be compared. Final coefficients and feature scales were fitted on 2014–2024 data only and saved before any test forecast was evaluated.

Table S30: Validation losses used to choose the EWMA decay and ridge penalty of the adaptive-volatility and direction-predicting models. Losses weight ticker, year, and horizon groups equally across the 2019–2024 validation blocks. Lower values are better within each selection task. The selected settings were an EWMA decay of 0.97 and the zero-drift limit.

Selection	Setting	Validation loss
EWMA decay	0.80	-2.921492
EWMA decay	0.90	-3.009741
EWMA decay	0.94	-3.044490
EWMA decay	0.97	-3.065558
EWMA decay	0.99	-3.064379
Ridge penalty	0.01	1.146523
Ridge penalty	0.1	1.143850
Ridge penalty	1	1.138475
Ridge penalty	10	1.136428
Ridge penalty	100	1.136142
Ridge penalty	1000	1.136112
Ridge penalty	Zero drift	1.136109

The two test periods differed in how current the stock data were at each origin. Historical close series for GS, LLY, and SPY shared the same recorded session grid, with 2,767 closes per ticker in 2014–2024 and 250 in 2025. The 2025 test updated lag features and variance using information through each origin while keeping fitted parameters fixed. The 2026 series began in April after a data gap. Its variance restarted from the 2014–2024 sample estimate and updated through the available April–July daily returns before evaluation. No daily return spanned the gap from December 2025 to April 2026. Within 2026, a daily return required closes on both adjacent trading sessions, and a missing observation left the variance unchanged. Feature windows used the last required number of valid daily returns, which could span more sessions when observations were missing. At evaluated 2026 origins, the most recent return used by the features was up to four calendar days old, whereas every 2025 origin had a return ending on the origin date.

Complete five-session and one-session scores cover all four candidates and both periods, including the direction-predicting rows that the main stock comparison omits (Tables S31 and S32). The direction-predicting and adaptive-volatility rows agree exactly because zero drift was selected. Their small median-error differences from the unchanged-price benchmark are Monte Carlo noise, since the population median of their forecast distribution equals the origin price. The three seeds measure simulation variation alone. The saved outputs include seed-level scores, date-level comparisons, input hashes, and settings.

Table S31: Complete five-session stock forecast scores for the four selected candidates: JumpHMM, the unchanged-price benchmark, and the adaptive-volatility and direction-predicting models. Each ticker has 245 origins in 2025 and 17 in August–September 2026. The MAE scores medians, and the RMSE scores means. Monetary values are in dollars per share. Coverage and width describe central 90% intervals. Scores average dates within each of three 10,000-path runs and then average the runs. The direction-predicting rows equal the adaptive-volatility rows because earlier-data selection chose zero drift.

Year	Stock	Model	Median MAE	Mean RMSE	CRPS	Coverage (%)	Width
2025	GS	JumpHMM	22.31	28.42	16.22	84.4	84.71
2025	GS	Unchanged	22.61	28.75	22.61	–	–

H Return Cutoffs and Sensitivity

Every JumpHMM price simulation used the truncated emissions in (1), with $b = 10$ as the primary cutoff and $b = 20$ as the wider sensitivity case. We set both cutoffs as stress assumptions before rerunning the affected experiments, without reference to the largest observed return. The truncation also applied to the state-inference likelihoods, and each experiment recomputed its pilot or ensemble normalization under each cutoff.

To show what the cutoffs mean for daily stock moves, we converted them to daily percentage returns using the pilot growth shift from the tests on later dates (Table S33). These limits are the widest possible daily returns over all fitted states, not forecast intervals. The removed mass is the probability cut from the standardized Student- t distribution, before state locations and scales are applied. Normalization constants differ slightly between experiments, and so do their daily limits.

Table S33: Daily return limits under the primary ($b = 10$) and wider ($b = 20$) cutoffs. The limits include the pilot growth shift from the tests on later dates and the $1/252$ year step. Removed mass is the probability excluded from the original Student- t emission, in percent.

Stock	b	Lower return (%)	Upper return (%)	Removed mass (%)
GS	10	-26.47	38.99	0.0171
GS	20	-42.73	81.83	0.0006
LLY	10	-21.23	38.98	0.0171
LLY	20	-38.22	82.11	0.0006

To test whether the results depended on the cutoff, we reran the GS and LLY illustrations, the IV ablation, both forecast cohorts, and the stock benchmarks at each cutoff with the same seeds and inputs. Any differences therefore come only from the changed cutoff and the recomputed normalization constants. We compared short-call loss summaries for the illustrations and for the full-factor ablation after ten trading days (Table S34). We also compared five-session full-factor option errors in the shorter-maturity cohort and JumpHMM stock scores (Table S35).

Table S34: Sensitivity of short-call P&L to the return cutoff b . Values are in dollars per share. The illustration uses 1,000 paths and P&L at expiration. The full-factor ablation uses 3,000 paths and P&L from closing after ten trading days. Expected shortfall ($ES_{5\%}$) averages outcomes at or below the 5% quantile.

Experiment	Stock	b	Mean P&L	5% quantile	$ES_{5\%}$
Ten-session ablation	GS	10	0.194	-35.194	-69.817
Ten-session ablation	GS	20	0.191	-35.203	-69.828
Ten-session ablation	LLY	10	6.260	-20.279	-45.182
Ten-session ablation	LLY	20	6.263	-20.273	-45.174
Terminal illustration	GS	10	-2.194	-86.183	-130.770
Terminal illustration	GS	20	-2.213	-86.243	-130.833
Terminal illustration	LLY	10	10.605	-51.956	-94.176
Terminal illustration	LLY	20	10.595	-52.006	-94.228

Table S35: Sensitivity of five-session option and stock forecast scores to the return cutoff b . Option MAE scores the full-factor forecast mean in the shorter-maturity cohort. Stock CRPS scores the JumpHMM forecast distribution in each period. Values are in dollars per share and use the same date and seed weighting as the main comparisons.

Quantity	Stock	$b = 10$	$b = 20$	Change
Option MAE, 2026	GS	4.193743	4.200236	+0.006492
Option MAE, 2026	LLY	11.587739	11.587747	+0.000008
